Introduction

Healthy women with family histories of breast cancer, who are at increased risk for developing the disease, have been reported to have reductions in immune function (reduced natural killer cell activity) compared to women without family histories of cancer in their families (Strayer, Carter & Brodsky, 1986). Consistent with theories of immune surveillance against neoplastic disease (Trinchieri, 1990), such reductions could contribute to the increased risk of breast cancer in women at familial risk for breast cancer. The reduced natural killer (NK) cell activity in women with family histories of breast cancer have previously been attributed solely to heritable deficits in immune function. However, the cumulative evidence that psychological factors (e.g., distress) can affect immune function (see review by Herbert & Cohen, 1993) suggests two ways in which psychoimmune mechanisms may contribute to the immune deficits in these women. First, as women at familial risk for breast cancer have been reported to be more distressed (see review by Lerman & Schwartz, 1993), distress induced immune suppression may contribute to their immune deficits. Second, women at familial risk for breast cancer may be psychobiologically more reactive and/or immunologically more sensitive to psychological challenges.

Two interrelated studies, one naturalistic and another experimental were conducted to address these issues.

Body

The Naturalistic Study: This study examined the contribution of distress-induced immune alterations to the reduced NK cell activity in healthy women with family histories of breast cancer. Three major questions were addressed: First, are healthy women, who are at familial risk for breast cancer, more psychologically distressed than women at normal risk (with no history of cancer in their families)? Second, do healthy women at increased familial risk for breast cancer also show evidence of reduced NK cell activity? Third, does increased emotional distress contribute to the reductions in NK cell activity associated with familial risk for breast cancer?

Procedure: Women with family histories of breast cancer in first degree relatives (Risk Group) and women without family histories of breast cancer in first or second degree relatives (Comparison Group) were recruited. These women were assessed on three separate days approximately one month apart (controlling for possible effects of menstrual cycles), at the same time of day (controlling for circadian effects). At each of these assessments the women completed standardized questionnaires (see study measures section 4.6 in the grant application), and after at least 30 minutes of rest, blood samples were collected for immune and endocrine measures (see sections 4.8 and 4.9 in the grant application).

Results: Data collection has been completed. A total of 244 women were recruited to the

Naturalistic study. We had proposed to recruit 120 women with family histories of breast cancer and 120 without family histories of breast cancer. Due to difficulties in finding women with family histories of breast cancer our final sample consists of 103 women with family histories of breast cancer and 141 women without family histories of breast cancer. Data entry has been completed, but, as this is a large data base, it has taken us longer than expected to verify the data. Consequently, we are behind in statistical analyses and in preparing manuscripts for publications. As the data have yet to be fully verified, it would be premature at the present time to report the results in this progress report as the results may not be accurate. We are therefore requesting a one year extension, without funds, to complete data verification and analyses.

The Experimental Study: This study examined the possibility that increased psychophysiological reactivity and/or immunological sensitivity to psychological challenges could contribute to the reduced natural cytotoxic activity in healthy women with family histories of breast cancer. Three major questions were addressed: First, do healthy women at increased familial risk for breast cancer also show increased psychological reactivity to experimental stressors (mental tasks)? Second, do healthy women with family histories of breast cancer evidence greater immunologic sensitivity to experimentally-induced distress? Third, is the increased immunological sensitivity to distress in healthy women at increased familial risk for breast cancer due to differences in sympathetic responses and/or cortisol responses to the experimental stressors?

Procedure: On the experimental days, participants were exposed to two consecutive mental tasks that have been shown to affect psychophysiological reactivity (i.e., self-reported distress, cardiovascular changes, endocrine changes) as well as immune measures (i.e., NK cell activity, lymphocyte proliferation) (e.g., Manuck, Cohen, Rabin et al., 1991; Stone, Valdimarsdottir, Katkin et al., 1993). Psychological distress is assessed (Profile of Mood States and Visual analog Scale; see Section 4.6 in the grant application) and blood samples for immune and endocrine assessments (see Sections 4.8 a 4.9 respectively in the grant application) were collected after a resting period and during and after stressor exposure at 15 to 30 minute intervals. Cardiovascular activity was assessed throughout the session.

Results: Data collection has been completed. A total of 91 have completed the experimental session which is 9 women less than we proposed to recruit. All the data have been entered but we are behind in verifying the data and in preparing manuscripts for publications. Initial data analyses suggest that women at increased risk for breast cancer are psychobiologically more reactive to the laboratory challenges. As we are behind schedule in analyzing the data, we are requesting a one year extension, without funds, to complete data analyses and manuscript preparations.

Conclusions

Data collection has been completed. Two hundred and forty-four women were recruited for the Naturalistic study and 91 women completed the Experimental study. All the data have been entered, however, as this is a large data base, it has taken us longer than anticipated verifying the data. Consequently, we are behind in data analyses and in preparing manuscripts for publications. Therefore, we are requesting one year extension, without funds, to complete data verification and analyses and to prepare manuscripts for publications.

With the support from this award #17-94-J-4139 we have published four papers and two papers have been submitted for publication.

ABSTRACT: This review focuses on studies that have examined the relation between psychosocial factors and secretory immunoglobulin A (s-IgA). Several studies have examined the relation between s-IgA and stressful circumstances ranging from major life events to minor daily events. The findings from these studies were often contradictory, since different experimenters reported different stress-related changes in s-IgA. The effects of stress reduction interventions, such as relaxation and imagery, on s-IgA levels have also been examined. Although these studies indicate that various interventions are associated with increases in s-IgA levels, methodological refinements are needed before more definitive conclusions can be made. The possibility that the relation between stress and s-IgA may be moderated by personality characteristics or mediated by psychological distress was supported in some studies. The review concludes with suggestions for future research.

Key words. Psychoneuroimmunology, secretory immunoglobulin A, distress, emotions, stress.

Introduction

In the late 1970s, behavioral medicine was defined as a discipline that would investigate the interplay between psychological factors and somatic health and disease (Schwartz and Weiss, 1978). Of course, movements exploring closely associated topics, such as the psychosomatic medicine movement, pre-dated and formed the groundwork for behavioral medicine. Interest in behavioral medicine has grown tremendously, spawning a number of societies and well over a dozen specialized journals.

As behavioral medicine research grew, research efforts shifted from the initial step of demonstrating relations between psychological or social factors and somatic outcomes to hypothesizing about and testing mediational pathways responsible for the observed associations. There are many models that have been proposed that summarize these relations (see reviews by Krantz *et al.*, 1985; Andersen *et al.*, 1994), one of which was advanced by Cohen and Williamson (1991). According to this model,

after an environmental stimulus has occurred (*e.g.*, loss of job), has been appraised (*e.g.*, as threatening to one's well-being), and after an affective response has occurred (*e.g.*, negative mood or depression), a series of behavioral and biological processes may come into play. One of these processes is change in behaviors potentially related to disease. For instance, increased use of alcohol or illicit medications, changes in eating patterns, reduced exercise, and less or poorer sleep have all been shown to relate to stress. One of the biological processes that may be affected by the preceding events is the autonomic nervous system. Changes in sympathetic and parasympathetic tone are related to numerous hormonal changes that are likely to influence susceptibility to disease. The process that is the focus of this review is the immune system. Of course, this system is responsible for keeping pathogens out of the body and for eliminating them once they have entered.

Given the importance of the immune system to health, it is not surprising that scientists with an interest

in behavioral medicine have targeted behavior-immune interactions. The extent of this focus is indicated by the creation of the discipline known as Psychoneuroimmunology (PNI). Several major texts have reviewed the PNI literature, there are societies devoted to the topic, and at least one journal publishes PNI work exclusively.

The work we discuss in this review falls into the domain of PNI and focuses on studies that have examined the relation between psychosocial factors and secretory immunoglobulin A (s-IgA). We first present an overview of s-IgA, followed by a discussion of the measures that have been used to index its activation. Summaries of the substantive work follow and are organized according to the nature of the psychosocial factors that have been manipulated or associated with s-IgA measures. These include stressful circumstances, relaxation and imagery, and psychological characteristics of the individual. A section on the possible mediational role of emotions, serving as a link between psychological factors and s-IgA, follows. A section on future directions for examining the relation between psychosocial factors and s-IgA concludes this review. The studies that were included in this review were identified through computerized search (Medline and PsychLit) and through inspection of reference lists from existing reviews and articles.

Secretory Immunoglobulin A

A glycoprotein called immunoglobulin A, or IgA, is the major immunoglobulin in the fluids that bathe the mucosal surfaces of the body and those surfaces that are the paths of entry of invading bacteria and viruses into the body (e.g., tears, saliva, gastrointestinal, vaginal, nasal, and bronchial secretions [Tomasi, 1970, 1976; Goldblum, 1990]). Secretory IgA (s-IgA) is different from IgA in serum in that it is much larger (Tomasi, 1976) and probably binds invading organisms more effectively than serum IgA. Most infectious agents enter the body through the mucosal surfaces, and the presence of s-IgA antibodies in the fluids helps to prevent infection, especially of the upper respiratory, intestinal, and urogenital tracts (Tomasi, 1976; Lamm *et al.*, 1995). For example, studies have shown that s-IgA antibody possesses antiviral activity (Dowdle *et al.*, 1971; Lamm *et al.*, 1995) and can prevent invasion by polio, measles, and rubella viruses (Ogra *et al.*, 1971; Ganguly *et al.*, 1973). In addition, there is evidence that s-IgA can prevent bacterial infections (Hedde and Rowley, 1975) and neutralize bacterial toxin (Waldman *et al.*, 1971; Goldblum, 1990). Secretory IgA is also implicated in dental diseases (Taubman and Smith, 1993). Degradation of s-IgA was associated with localized juvenile periodontitis (Gregory *et al.*, 1992). Similarly, caries-prone persons have been found to have lower salivary IgA concentrations than caries-resistant persons (Lehner *et al.*, 1967; Gregory *et al.*, 1992), and deficiencies in s-IgA have been identified as one of the factors

responsible for the frequent oral infections in patients with AIDS (Muller *et al.*, 1992).

Measurement of s-IgA in Psychoneuroimmunology Studies

The two most commonly used measures of IgA production in the field of psychoneuroimmunology have been s-IgA concentration and s-IgA secretion rate. Secretory IgA concentration is the amount of total IgA protein that is present in a certain volume of saliva (i.e., $\mu\text{g/mL}$), whereas s-IgA secretion rate refers to the amount of IgA protein detected *per unit time* (i.e., $\mu\text{g/min}$).

Although these measures have been used rather frequently in conjunction with psychosocial factors (as will be shown below), questions have been raised about their value as an index of immune system functioning. Stone *et al.* (1987b) discussed several potential problems with measures of s-IgA concentration and secretion rate, including: the effect of saliva flow rate on concentration; a possible deterioration of s-IgA proteins by proteases in the mouth; and, on a conceptual level, the meaning of total s-IgA protein as a measure of immune protection. Jemmott and McClelland (1989), who are the authors of the majority of the studies discussed in Stone *et al.*'s (1987b) paper, replied in a subsequent paper. They argued that salivary flow rate might not be as large a problem, especially in unstimulated collection conditions, that the studies were consistent in the relation of s-IgA changes to psychological factors, that s-IgA might not deteriorate in the mouth, and that total s-IgA protein was shown to be a reasonable measure.

Because these are debated issues (and because we have taken a position on some of these issues), we recommend that readers evaluate the arguments for themselves. However, we would like to comment briefly on the saliva flow issue. As stated above, one of the potential problems with using s-IgA measures is that saliva flow can affect both concentrations of s-IgA and s-IgA secretion rate. At least in some situations, it has been demonstrated that when saliva flow rate is artificially stimulated (with, for example, lemon drops), s-IgA concentrations decrease with increased flow, while the s-IgA secretion rate increases with increased flow rate (Brandtzaeg, 1971). Similar findings have been observed when saliva flow was not artificially stimulated (Graham *et al.*, 1988; Kugler *et al.*, 1992; Evans *et al.*, 1993). The relations between saliva flow rate and s-IgA concentration and secretion rate are particularly important, since autonomic arousal associated with stress or negative affect may influence saliva flow rate (Stone *et al.*, 1987b), although the directionality of the effects is uncertain.

An issue in this debate that has not received much attention concerns the measurement of saliva volume. In our experience, measuring saliva flow is not a straightforward task, and we question the reliability as well as

the validity of such measurement. It is difficult for a subject to drool into a vial, and we speculate that the amount of saliva collected is related to a number of factors concerning how the subject accomplishes the task. We know of no test-retest data demonstrating that flow is a reliable measure. This is an area that deserves some attention in the future.

On conceptual grounds, an alternative to the measurement of all s-IgA protein in a sample of saliva has been proposed by Stone *et al.* (1987b). They argue that the s-IgA antibody response to a particular antigen, rather than s-IgA protein, should be evaluated. One of the antigens that Stone and his colleagues have used in their studies is a harmless protein, rabbit albumin. According to these authors, the antibody responses to a novel antigen (*e.g.*, rabbit albumin in samples of individuals who have not previously eaten rabbit) are analogous to those responses to a pathogen that would occur if an individual were infected by a virus or a bacterium.

To date, there has been no confirmation of the relative merits of the use of total s-IgA vs. specific s-IgA antibody in terms of response to a known antigen, since only the Stone research group has used the latter methodology. Jemmott and McClelland (1989) have raised issues concerning this measure, given that it is based on a ratio of specific antibody to total s-IgA protein. Those authors are concerned that the overall amount of s-IgA—rather than the relative growth of s-IgA antibody—is the important factor. As will be shown below, there are many studies that have shown associations between psychological stressors or other conditions and s-IgA levels, and there have been two separate studies that have shown such associations with s-IgA antibody to a novel antigen. In those studies, both measures of s-IgA were available, and the specific antibody measure demonstrated stronger associations with stress variables than did the total protein measure. Nevertheless, no data are available that address the issue of which is a better empirical predictor of health status.

Stressful Events

Stressful events, ranging from major life events to daily events, have been shown to be related to illness onset in a number of studies (Cohen and Williamson, 1991). From the perspective of understanding the role of s-IgA, it is important to note that some of these studies had upper respiratory illness (URI) as the outcome variable. These studies support the idea that life stressors may be related to immunological processes, although compelling arguments can also be advanced that behavioral factors—such as sleeping, alcohol consumption, smoking, etc.—also mediate the stress-illness association (see Cohen *et al.*, 1995). Several studies, reviewed below, examined the possibility that stressful life events (major and daily) affect s-IgA.

TOTAL EVENT STUDIES

We start with studies that have used event checklists and created predictor variables representing the total amount of stress associated with those events an individual experiences. In general, studies have not found a relation between major life events (*e.g.*, death of a spouse) and s-IgA (Kiecolt-Glaser *et al.*, 1984; Graham *et al.*, 1988) or between daily hassles (defined as minor daily annoyances, but that are usually measured in a retrospective manner over a 30-day period [see Kanner *et al.*, 1981]) and s-IgA (Kubitz *et al.*, 1986; Farne *et al.*, 1994). A complex relation between s-IgA concentration and daily hassles was observed in Martin and Dobbin's (1988) study of daily hassles. In this study, hassles and s-IgA were assessed during two sessions 90 days apart. Frequency of hassles assessed during the first session was negatively correlated with s-IgA concentration assessed in both sessions. On the other hand, no relation was observed between frequency of hassles and s-IgA concentration assessed during the second session.

Two studies have examined how minor stressors measured on a daily basis affect s-IgA. In Evans *et al.*'s (1993) study, subjects completed the Student's Assessment of Daily Experience (SADE) questionnaire daily for 14 days. Each of the 27 events on the SADE that occurred during the day was rated by subjects on a six-point scale from "extremely desirable" to "extremely undesirable". On each day, subjects also provided a timed saliva sample for assessments of s-IgA concentration and s-IgA secretion rate. When the data were aggregated over the two-week period, a negative correlation was observed between undesirable events and s-IgA concentration, and a positive correlation was observed between desirable events and s-IgA concentration. That is, the mean level of s-IgA concentration across all days was negatively correlated with the average number of undesirable events for the same period and positively correlated with the average number of desirable events. A parallel finding was observed for s-IgA secretion rate. On the other hand, analyses examining the day-to-day association between events and s-IgA concentration and secretion rate (within subjects as opposed to the previous between-subjects analyses) revealed that while undesirable events were associated with higher concentrations of s-IgA, undesirable events were unrelated to s-IgA secretion rate. Desirable events were unrelated to both s-IgA concentration and s-IgA secretion rate. These findings are troublesome, since the two types of analyses produced divergent results.

In contrast to Evans' study of total s-IgA, Stone *et al.* (1994) used the specific antigen model of s-IgA. They exposed 94 adult males to a harmless protein (rabbit albumin) and examined whether daily events affected s-IgA antibody response to the rabbit albumin. The immunization procedure involved daily ingestion of a

capsule containing rabbit albumin for 12 weeks. Each day, subjects also completed an 80-item event checklist that was organized in sections dealing with work, leisure, friends, spouse, children, household activities, finances, self, and two write-in items. A further refinement of the event assessment was that subjects' spouses aided them in the accurate completion of the event checklist to ensure the most accurate and objective reports of daily events (see Stone and Neale, 1982, for a description of the questionnaire development). As an assessment of the subjective experience of the event, each event that occurred during the day was rated on a six-point scale, from "extremely desirable" to "extremely undesirable".

After completing the questionnaire, subjects collected saliva that was assayed for s-IgA antibody activity to the rabbit albumin. Results from within-subject analyses revealed that the frequency of desirable events was related to more s-IgA antibody production, whereas the frequency of undesirable events was related to less s-IgA antibody production. In other words, on days when there were relatively more undesirable events than usual, s-IgA antibody levels were lower than on days without undesirable events. The authors also examined whether daily event content predicted s-IgA antibody production. Undesirable work events and desirable leisure and household events were more strongly related to s-IgA antibody than were events in other categories. Last, desirable events on the previous two days predicted subsequent increases in s-IgA antibody production, but for undesirable events, only the same-day events inversely predicted s-IgA antibody production. It is important to note that days with upper respiratory symptoms were eliminated from these analyses; this procedure has not been carried out in other daily studies.

SINGLE-EVENT STUDIES

Rather than investigating how the number of major stressful life events or day-to-day events affects s-IgA, several studies have examined the impact of a single stressful circumstance, academic pressure due to examinations. Two studies reported that academic stress is associated with reductions in s-IgA. Jemmott *et al.* (1983) collected saliva from 47 dental students. Five collections were made over an 11-month period: three collections during examination periods and two during low-stress periods. The authors found that s-IgA secretion rate was lower during the three exam time points compared with the two low-stress time points. Since data collection was spread over an 11-month period, it is possible that these effects were due to seasonal variation in s-IgA secretion. To rule out this possibility, Jemmott and Magloire (1988) conducted a second study using a shorter time interval. Saliva was collected from 15 undergraduates five days prior to their exam, during their exam period, and two weeks after their exam. S-IgA concentration, s-IgA

secretion rate, and s-IgA statistically adjusted for saliva flow were lower during the exam period compared with the measures collected before and after the exam.

Increases in s-IgA have also been observed after examination. McClelland *et al.* (1985) found that both s-IgA concentration and norepinephrine concentration in saliva increased in 46 students both immediately after and 1 3/4 hours after an exam, compared with baseline measures collected several days after the exam. The increase in norepinephrine concentration did not account for the increase in s-IgA concentrations, since the correlation between these two measures was non-significant. Evans and colleagues (1993) collected saliva from 18 students in two consecutive weeks. In the second week, all students had to give a presentation. During both weeks, saliva was collected 4 times one hour apart, and in the second week, saliva was collected immediately after the presentation. The authors found that there was a trend ($p = 0.10$) for s-IgA secretion rate to increase from week 1 to week 2 to post-presentation. A parallel increase was observed in salivary cortisol concentrations. However, since the authors did not examine the relation between s-IgA secretion rate and salivary cortisol, it is not clear if the increase in salivary cortisol contributed to the increase in s-IgA secretion rate.

No change in s-IgA following an examination has also been observed. Kiecolt-Glaser and colleagues (1984) collected saliva from 65 medical students a month before a final exam and again on the first day of the final exam. No change in s-IgA concentration was observed from pre-test to post-test assessments. Mouton *et al.* (1989) collected saliva from 44 dental students on four occasions over two academic years: two collections during low-stress periods and two collections during examination periods. Results indicated that academic examinations affected s-IgA secretion rate only when the final examination and the summer vacation samples were compared (s-IgA secretion rate was lower during the final examination than during the summer vacation). On the other hand, no difference in s-IgA secretion rate was observed between samples collected during midterm exams and samples collected during midterm break.

SUMMARY

The pattern of results in these studies is neither consistent nor simple. Many studies that examined major life events and daily hassles used retrospective designs in which subjects indicated how many life events or hassles had occurred over a prior time period. It is therefore possible that recall ability and/or memory biases accounted for the lack of association between s-IgA and life events. The studies that examined the impact of academic stressors on secretory IgA are difficult to evaluate because they differ in several key variables. One of these variables is the timing various experi-

menters chose to collect their pre-stress, stress, and post-stress measures. For example, McClelland *et al.* (1985) collected the baseline measure a few weeks after the exam and the stress measure immediately after an exam and 1 3/4 hours after the exam, whereas Jemmott and Magloire (1988) collected their baseline measure five days prior to the exam and the stress measure during the examination period. It is certainly possible that changes in secretory IgA observed at some of these times might not be present at other times. It is of interest that the two studies (McClelland *et al.*, 1985; Evans *et al.*, 1994) that observed increases in s-IgA following the academic stressor collected their stress measures immediately following the completion of the exam. It is possible that termination of an acute stressor results in increased s-IgA; however, before any conclusion can be reached, studies need to be conducted that will allow for the exploration of timing factors.

Another variable on which these studies differ is the procedure used to determine s-IgA. McClelland *et al.* (1985), for example, measured s-IgA concentration, whereas Mouton *et al.* (1989) measured s-IgA secretion rate. Only two of the studies (Jemmott and Magloire, 1988; Mouton *et al.*, 1989) measured saliva flow rate. Examination stress has been found to affect flow rate (Bates and Adams, 1968), and, as discussed above, s-IgA concentrations and secretion rate are differentially affected by saliva flow rate. Therefore, it is difficult to interpret the findings that did not take saliva flow rate into account, since the effects of stress on saliva flow could have accounted for the changes observed in s-IgA. The mechanism whereby stressful events affect s-IgA is not clear. It has been hypothesized that stress affects the immune system through its impact on the hypothalamic-pituitary-adrenal axis and the sympathetic nervous system (see review by Rabin *et al.*, 1989; Ader and Felten, 1995; Weigent and Blalock, 1995; Bedovsky and Rey, 1996). In the studies reviewed above, changes in salivary cortisol (Evans *et al.*, 1994) and in salivary norepinephrine (McClelland *et al.*, 1985) were observed in parallel to changes in s-IgA levels. However, it is not clear if these stress-induced hormonal changes contributed to the stress-induced changes observed in s-IgA levels, since McClelland *et al.* (1985) found no relation between salivary norepinephrine concentration and s-IgA concentration, and Evans *et al.* (1994) did not examine the relation between salivary cortisol concentration and s-IgA secretion rate.

Relaxation and Imagery

The evidence that stress can affect the immune system, including s-IgA, raises the possibility that positive experiences, the opposite of stressful ones, could also affect the activity of the immune system (Jasnoski and Kugler, 1987; Zakowski *et al.*, 1989; Van Rood *et al.*, 1993).

Several behavioral intervention techniques have been found to influence physiological processes, such as heart rate and blood pressure (Blumenthal and McKee, 1987; Basmajian, 1989). The studies reviewed below examined whether it is possible to increase the levels of s-IgA by stress-reducing interventions.

Green and Green (1987) randomly assigned 50 college students to relaxation groups (relaxation response, guided visualization, back massage) or control groups (lying quietly with eyes closed or touching-control group). Saliva samples were collected before and immediately after the session, which lasted 20 minutes. Results indicated that there was a significant increase in s-IgA concentration from pre- to post-treatment in the relaxation groups, but no change was observed in the control groups. Salivary cortisol was not affected by the relaxation training, suggesting that the changes in s-IgA were independent of changes in cortisol.

In another study, the same authors (Green *et al.*, 1988) examined the effect of daily relaxation on several parameters of the immune system, including s-IgA secretion rate. Forty subjects were randomly assigned to practice one of three relaxation techniques (relaxation response while sitting up, relaxation response while lying down, and guided visualization while lying down) daily for three weeks. Saliva samples were collected before and after 20 minutes of supervised relaxation on day 1 and on day 22 or after three weeks of practicing the relaxation. Since there were no differences among the relaxation groups, the data from the three treatments were combined. In confirmation of previous findings, a significant increase in s-IgA secretion rate was observed immediately after 20 minutes of relaxation practice compared with levels right before the relaxation. In addition, long-term practice effects were also observed: s-IgA secretion rate increased significantly from day 1 to day 22. These changes in s-IgA secretion rate appeared to be independent of psychological distress, since no change was observed in anxiety as measured by the anxiety scale on the Hopkins symptom checklist (Derogatis *et al.*, 1974) and the Taylor manifest anxiety scale (Taylor, 1951).

Jasnoski and Kugler (1987) randomly assigned 30 undergraduates to two relaxation groups or a control group. One of the relaxation groups was trained in progressive relaxation and focused breathing, while the other relaxation group was also trained in imagining powerful, positive immune function. The control group was instructed to discriminate between two tones presented at variable intervals. Saliva samples were collected before and immediately after the training sessions. After a single one-hour session, an increase was observed in s-IgA in both of the relaxation groups, but no change was observed in the control group. Norepinephrine and epinephrine from saliva and serum were also assessed, as was cortisol in saliva. However,

none of these neuroendocrine measures accounted for the s-IgA difference between the relaxation and the control groups.

Rider *et al.* (1990) examined whether imagery directed at biological mechanisms is more effective in increasing s-IgA concentration than non-directed imagery. Forty-five students were randomly assigned to three groups. Members of Group 1 were instructed to focus their imagery on their immune system while they listened to an audio cassette containing imagery instruction followed by music. Group 2 received the same music and general non-specific imagery instructions, and Group 3 underwent no treatment. Subjects came for three sessions scheduled three weeks apart (days 1, 21, and 42), and each session lasted 17 minutes. Saliva samples were collected at the beginning of each session and again at the end of each session. Subjects in the treatment groups were provided with cassette tapes to which they were instructed to listen at home on a bi-daily basis for six weeks.

In both treatment groups, s-IgA concentration increased within each session, yet no change was observed in the control group. Changes in s-IgA concentration across the sessions were not examined; however, inspection of the means suggests that the treatments did not increase s-IgA across sessions. The interventions decreased psychological distress as measured by the Profile of Mood States (McNaire *et al.*, 1971), but no change was observed in sympathetic nervous system response as measured by skin temperature. The treatment groups reported fewer symptoms during the study; however, the particular symptoms affected did not appear to be immune-related (breathing difficulty, jaw clenching, and rapid heartbeat). In their second study, Rider and Welden (1990) used live, improvised music instead of taped music, and only one 10-minute session was conducted. After the intervention, concentrations of s-IgA were higher in the music+imagery group than in either the music-only group or the control group. The music-only group did not differ from the control group.

One study has examined whether relaxation affects s-IgA in children. Olness *et al.* (1989) assigned 57 children to two treatment groups and a control group. During the treatment session, which lasted 25 minutes, both treatment groups learned self-hypnosis. In addition, one of the groups was given specific suggestions to increase salivary immunoglobulins. The control group subjects were engaged in conversation for 25 minutes. Children who received the specific suggestions had significantly higher concentrations of s-IgA after the training session. No change was observed in the other two groups.

Groer *et al.* (1994) examined the effects of a 10-minute massage and back rub on s-IgA concentration and s-IgA secretion rate. Eighteen subjects who were assigned to the experimental group received a 10-minute back massage,

and 14 subjects who were assigned to the control group rested for 10 minutes. Although the treatment did not affect anxiety as measured by the Spielberger state/trait anxiety inventory (Spielberger, 1983), an increase in s-IgA concentration was observed in the experimental group, and a similar trend was observed for s-IgA secretion rate.

SUMMARY

These studies suggest that various interventions can induce short-term increases in s-IgA levels. However, methodological refinements are needed before more definitive conclusions can be made. The long-term effects of these interventions on s-IgA levels are not clear, since most of the studies collected saliva only immediately before and immediately after the intervention. Of the two studies (Green *et al.*, 1988; Rider *et al.*, 1990) that assessed s-IgA a few weeks after their intervention, only one (Green *et al.*, 1988) reported increased levels of s-IgA as long as 22 days after the completion of the intervention. Furthermore, future studies need to assess variables such as frequency of practice and compliance with treatment regimens. Because none of the studies assessed whether the individuals used relaxation skills in stressful situations, there is no experimental evidence that coping (*e.g.*, relaxation) intervenes between stress exposure and s-IgA.

The mechanism whereby these interventions affect s-IgA is not yet clear. It is possible that these interventions affect subjective distress and physiological arousal, which in turn may affect s-IgA. However, of the three studies (Green *et al.*, 1988; Rider *et al.*, 1990; Groer *et al.*, 1994) that assessed subjective distress, only one study (Rider *et al.*, 1990) observed a decrease in subjective distress after the intervention, and the two studies (Green and Green, 1987; Jasnoski and Kugler, 1987) that included neuroendocrine assessments did not observe changes in these measures following the intervention. Clearly, studies are needed that systematically investigate the mechanism underlying the effects of psychosocial interventions on the s-IgA.

One possible confounding factor in these studies is saliva flow rate. Relaxation has been found to affect saliva flow rate (Carlson, 1986), and saliva flow rate can affect both s-IgA concentration and secretion rate. Since none of the investigators corrected their s-IgA measures for flow rate, the possibility that the change in secretory IgA was due to flow rate changes cannot be ruled out.

Psychological Characteristics of Individuals

In earlier reports on the relationship between stress and illness, it was assumed that stressors affected all individuals similarly. However, since the correlation between stressful life events and illness was found to be generally low, researchers became more interested in moderating and/or mediating variables that might augment or

reduce the effects of stressful variables. The studies reviewed below have examined the possibility that variables that have been shown to moderate the stress and illness association also moderate the relation between stress and s-IgA concentration and secretion rate.

SENSE OF HUMOR

This characteristic has been found to moderate the relation between stressful life experiences and psychological distress (Lefcourt and Martin, 1986). The possibility that sense of humor may also affect s-IgA has been examined in several studies. Martin and Dobbin (1988) examined whether sense of humor moderates the effects of daily hassles on s-IgA concentration. Approximately 90 days apart, 40 undergraduates provided saliva samples and completed a daily hassles scale. In addition, they completed four humor questionnaires (situational humor response, coping humor, sense of humor, and liking of humor). Sense of humor was unrelated to s-IgA concentration, but there was some support for the stress-buffering effects of humor: The negative association between hassles assessed at time 1 and s-IgA concentration assessed at time 2 was stronger for individuals with low scores on the humor questionnaires than for individuals with high scores on the humor questionnaires.

Another way that humor has been explored is shown in an investigation of exposure to humorous stimuli in individuals with a good sense of humor. Dillon *et al.* (1985) observed an increase in s-IgA concentration among 10 subjects immediately after they had watched a humorous videotape but not after they had watched a didactic control tape. Change in s-IgA was inversely related to sense of humor as measured by the Coping Humor Questionnaire (CHQ; Martin and Lefcourt, 1984). On the other hand, in contrast to Martin and Dobbin's (1988) finding, baseline levels of s-IgA were positively related to sense of humor. Similarly, Dillon and Totten (1989), who studied 17 women before and after they gave birth, found a positive association between s-IgA concentration and sense of humor as measured by the CHQ.

Lefcourt *et al.* (1990) conducted three studies to examine the relation among sense of humor, humorous stimuli, and s-IgA. In all three studies, subjects watched humorous movies and provided saliva samples before and after the presentation of the movies. The movie presented and methods to assay s-IgA along with the timing of baseline assessments varied between the studies. In all three studies, subjects completed two humor scales, the Situational Humor Response Questionnaire (SHRQ; Martin and Lefcourt, 1984) and the Coping Humor Scale (CHS; Martin and Lefcourt, 1993). There was an increase in s-IgA from before to after the presentation of the humorous movie in all three studies. None of the studies found a relation between sense of humor and baseline levels of s-IgA. Subjects who scored high on the CHS in

study 1 had a significant increase in s-IgA concentration, whereas no change was observed among subjects who scored low on the this scale; this relation was not observed in studies 2 and 3. A marginally significant interaction was found in study 3 between SHRQ and the condition that reflected the greater change for subjects with high SHRQ scores; this interaction was not observed in studies 1 and 2.

Two studies examined the effects of weeping and laughing on s-IgA. Labott *et al.* (1990) showed 32 undergraduate women sad and humorous videotapes. Half of the subjects were told to express their emotions, and half of the subjects were told to inhibit their emotions. Seven control subjects watched documentary tapes. Seven subjects in the expression condition were excluded from the analyses, since they failed to express their emotions overtly, and seven inhibition subjects were excluded, since they expressed their emotions overtly. Individuals who cried during the sad movie had significantly lower s-IgA concentrations after the movie compared with both the control subjects and the subjects who inhibited overt expression of crying. On the other hand, the humorous movie was associated with increased s-IgA concentration regardless of the expression or inhibition of overt laughter. Sense of humor, as assessed by the Coping Humor Questionnaire (Martin and Lefcourt, 1983), was not associated with initial or baseline s-IgA concentration values. To examine further the effects of emotional crying on s-IgA concentration, Martin *et al.* (1993) showed 42 undergraduates a sad movie. An increase was seen in s-IgA from pre- to post-movie in subjects who reported that they had not cried during the movie. No change was seen in s-IgA among subjects who reported that they had had tears in their eyes during the movie or among subjects who reported that they had tears down their faces or sobbed during the movie.

INHIBITED AND STRESSED POWER MOTIVATION

These concepts have been studied extensively by David McClelland and his co-workers. Individuals high in inhibited power motivation are assertive and hard-driving, but inhibited in direct expression of aggression. Such people are more vulnerable to disease than others, especially if they have experienced or are currently under power-related stress (*i.e.*, life events that challenge or threaten the individual's ability to perform powerfully or impress others). In a series of studies, McClelland and colleagues have examined power motivation and s-IgA.

McClelland *et al.* (1980) explored the relation between power motivation, stressful life events, upper respiratory infection, and concentrations of s-IgA. Twenty-seven male college students were assessed twice 48 to 72 hours apart. During the first session,

subjects provided saliva samples and completed a modified version of the Social Readjustment Rating Scale (SRRS; Holmes and Rahe, 1967) and an illness inventory. The items of the SRRS were classified as power events, affiliative events, both, or neither. During the second visit, subjects provided urine samples for assessments of epinephrine and norepinephrine, after which they participated in a mildly stressful task for 2 1/2 hours, followed by additional urine and saliva sampling. Seven subjects were classified as high in need for power, high in inhibition, and high in reported power stress (HHH group). The HHH subjects reported more illnesses in the past 6 to 10 months, had lower s-IgA on the first assessment, and had higher epinephrine excretion rates (assessments before and after the task were averaged) than other subjects. On the other hand, the HHH subjects did not differ from other subjects in norepinephrine excretion rate or in the concentration of s-IgA after the task.

In a similar study with 133 prisoners, McClelland *et al.* (1982) found that prisoners who scored high on need for power and high on life stress had a lower concentration of s-IgA and reported more illnesses in the past 12 months. In contrast to the 1980 study, prisoners who were also high on inhibition had higher concentrations of s-IgA and reported fewer illnesses in the past 12 months than prisoners low on active inhibition.

In two of the examination studies reviewed above, McClelland and co-workers investigated whether examination stress had greater impact on s-IgA among students high in need for power. The first study (Jemmott *et al.*, 1983) assessed s-IgA secretion rate on five occasions (three exam points and two low-stress points) over an 11-month period. A continuing decline in s-IgA secretion rate through the final low-stress period was observed among the students classified as high in need for power and high in active inhibition, whereas s-IgA secretion rate recovered during the low-stress periods in all other subjects. Moreover, students classified as high in need for affiliation and low in active inhibition had higher s-IgA secretion rates on all five assessments compared with all other students. In their second study, McClelland *et al.* (1985) failed to find consistently higher s-IgA levels among individuals classified as high in need for affiliation. A difference in s-IgA concentration after taking an exam was observed between individuals who differed on power motivation: Students whose need for power was stronger than their need for affiliation had lower s-IgA 1 3/4 hours after their exam as compared both with baseline measures collected a few days after the exam and with students whose need for affiliation was higher than their need for power. Students with stronger need for power also had greater increases in norepinephrine in response to the examination, but the increase in salivary norepinephrine was not related to s-IgA concentration.

LOCUS OF CONTROL

This concept is defined as a person's belief that he or she can control desired or undesired outcomes (such individuals have an internal locus of control) or that such outcomes are the results of fate, luck, or other forces (external locus of control). Kubitz *et al.* (1986) examined the relation among health, locus of control, daily hassles, and levels of s-IgA concentration. Twenty-nine subjects provided saliva samples and completed both the Multi-Dimensional Health Locus of Control Scale (MHLC; Wallston *et al.*, 1976), a measure of locus of control over health outcomes, and the Hassles Scale (Kanner *et al.*, 1981), a measure of frequency and intensity of stressful situations in the past month. The results indicated that while there was no relation between levels of s-IgA concentrations and daily hassles, there was an inverse relationship between concentrations of s-IgA and internal locus of control. An interaction between locus of control and daily hassles was also obtained: Individuals high on internality and with high levels of daily hassles had lower levels of s-IgA than individuals low on internality and with high levels of daily hassles. As discussed by the authors, the finding that subjects with more internal locus of control had lower levels of s-IgA was surprising, since several studies have shown that internally oriented individuals report fewer illnesses (Wallston and Wallston, 1982). Last, menstrual cycle status may influence levels of s-IgA, since higher levels of s-IgA were observed for female subjects in the first half of their cycle than for female subjects in the second half of their cycle.

HARDINESS

This concept has been defined as a composite of three tendencies: sense of internal locus of control, sense of purpose and involvement, and a tendency to view changes as incentives or opportunities for growth (Kobasa, 1979, 1982). Several studies have shown that hardiness plays an active role in protecting individuals from stress (Kobasa, 1979, 1982; Kobasa *et al.*, 1981). In the study by Dillon and Totten (1989), reviewed above, hardiness was not related to s-IgA concentration or to upper respiratory tract infection.

SOCIAL SUPPORT

Among the variables discussed in this section of the paper as having an association with health status, social support has by far received the most empirical support. Generally, the idea is that higher levels of social support are related to positive health outcomes (Cohen and Wills, 1985), but there are more complex hypotheses as well. According to the main-effect hypothesis, social support is beneficial for health regardless of whether the individuals are exposed to stress. Alternatively, according to the buffering hypothesis, social support has a

beneficial effect on health only when individuals are exposed to stress. Existing studies support both of these hypotheses (Cohen and Wills, 1985). The study by Jemmott and Magloire (1988), reviewed above, included a measure of social support. Consistent with the main-effect model, the authors found that students who reported adequate social support had higher concentrations of s-IgA across all three assessments (pre-exam, exam, post-exam). On the other hand, in contrast to the buffering hypothesis, the relation between adequacy of support and s-IgA concentrations did not differ in the exam period compared with the pre- and post-exam periods. Two of the studies reviewed above included measures of loneliness. In both studies, loneliness, which may reflect low social support, was unrelated to s-IgA concentration (Kiecolt-Glaser *et al.*, 1984) and to s-IgA secretion rate (Green *et al.*, 1988).

SUMMARY

Taken together, these studies demonstrate that in order to maximize the predictive value of stress-immune function research, experimenters need to include potential moderators and mediators in their study designs. However, integrating and drawing conclusions from these studies is difficult, for a number of reasons, described below.

Sense of humor was one of the most-examined personality variables. While humorous movies were consistently found to induce short-term increases in s-IgA, the results for sense of humor were inconsistent. Individuals who scored high on measures of sense of humor were found to be more responsive to comic material (Lefcourt *et al.*, 1990), less responsive to comic material (Dillon *et al.*, 1985), or responded the same way to comic material as individuals who scored low on sense of humor (Lefcourt *et al.*, 1990). In addition, it is not clear if sense of humor is associated with higher levels of resting levels of s-IgA, since some authors found a positive relation (Dillon *et al.*, 1985), while others reported no relation (Labott *et al.*, 1990; Lefcourt *et al.*, 1990). These contradictory findings may be due to the fact that the studies differed in several key variables, including the measures used to assess sense of humor, movies selected to elicit humor, and methods used to assay s-IgA.

Inhibited power motivation is another personality variable that has been extensively studied. All of these studies were correlational and as such do not address the issue of causality. Importantly, the findings were often inconsistent. Individuals who scored high on inhibition (in combination with need for power and power stress), for example, were reported to have lower levels of s-IgA concentrations in some studies (McClelland *et al.*, 1980), yet higher levels of s-IgA concentrations were observed in other studies (McClelland *et al.*, 1982). Moreover, high levels of affiliative need were found to be associated with

higher levels of s-IgA secretion rate during both stress and non-stress periods (Jemmott *et al.*, 1983), but this finding was not replicated for s-IgA concentration (McClelland *et al.*, 1985). Again, these discrepancies may be due to the different subject populations used in these studies as well the different methods used to assay s-IgA.

It is implied in all of these studies that individuals with different personality profiles differ in how they appraise and cope with the stressors they encounter. For example, individuals high in inhibited power motivation are expected to appraise and cope differently than subjects low in need for power. Thus, consistency in coping across different situations and individuals is implied by these authors. However, the efficacy of using personality traits in predicting behavior has been challenged (Michel, 1968, 1973). In general, individuals are characterized more by variability than stability in coping (Folkman and Lazarus, 1980; Lazarus and Folkman, 1984). We found no direct evidence that coping affects or alters the stress-induced changes in s-IgA.

The finding by Jemmott and Magloire (1988) that social support was associated with higher levels of s-IgA is interesting, since several studies have demonstrated that social support is related to health outcomes. However, since this was the only study that examined the role of social support, it is not clear if social support affects s-IgA regardless of whether the individual is undergoing stress or if it also buffers the effects of stress on s-IgA. Clearly, studies are needed that replicate and extend (*i.e.*, manipulate social support) this finding.

The Medial Role of Emotional Distress

The above studies lend some support to the hypotheses that stressors and psychobehavioral interventions can affect s-IgA. But how do stressors and psychobehavioral interventions result in s-IgA alteration? One possible pathway is that stressors and interventions affect psychological distress, which in turn affects biological systems (*i.e.*, nervous system, neuroendocrine system) that influence immunologic processes, including s-IgA (see Stone *et al.*, 1996). Several of the studies reviewed above did not include measures of psychological distress and could not address this hypothesis. Those that did either found no changes in psychological distress or did not examine whether changes in psychological distress mediated the changes in s-IgA levels. For example, one study (Rider *et al.*, 1990) found that psychological distress was reduced after a psychobehavioral intervention, and three studies (Jemmott *et al.*, 1983; Mouton *et al.*, 1989; Evans *et al.*, 1994) found that academic examination increased psychological distress. However, since none of these studies examined the relation between changes in psychological distress and changes in s-IgA, there is no evidence that changes in s-IgA observed after various interventions

and stressors are mediated by changes in psychological distress.

The strongest support for the hypothesis that psychological distress mediates the relation between stress and s-IgA comes from Stone *et al.* (1994), described above. A recent analysis of the data from Stone *et al.* (1996) used analyses specifically designed to address third-variable mediational questions. Results indicated that the negative relation between undesirable events and s-IgA antibody production was mediated by increases in negative mood, and the positive relation between desirable and s-IgA antibody production was mediated by increases in positive mood.

Other studies have examined the impact of positive and negative affective states without an explicit stressor. Stone *et al.* (1987a) examined the relation between daily fluctuations in mood and s-IgA antibody production. Throughout an eight-week period, 30 male dental students ingested a daily capsule containing a purified rabbit albumin, and three times a week over the eight-week period they completed the Nowlis Mood Adjective Checklist (Nowlis, 1965) and provided saliva samples that were assayed for IgA antibody production to the albumin. Examination of s-IgA antibody responses showed that antibody response was lower on days with high levels of negative mood relative to days with low levels of negative mood. On the other hand, antibody production was higher on days with high levels of positive mood relative to days with low levels of positive mood. Stone *et al.* (1994) replicated their finding: Positive affect was associated with higher levels of antibody production, and negative mood was associated with lower levels of antibody production. As raised by the authors (Neale and Stone, 1989), one possible explanation for these findings is that negative daily events affect the fluctuation in mood, which in turn suppresses s-IgA antibody production. This is an unlikely explanation, since the authors found, in one of their subsequent studies, that the relationship between s-IgA antibody production and mood remained significant after daily events were controlled for (Stone *et al.*, 1996).

In the Evans *et al.* (1993) study reviewed above, 12 subjects completed the Nowlis Mood Adjective Checklist and provided saliva samples daily for 14 days. No relation was observed between affect (positive and negative) and s-IgA concentration and secretion rate when the data were averaged across all days. On the other hand, within-subject analyses showed that s-IgA concentrations and secretion rates were higher on days with high levels of negative affect. Although not significant, there was a trend for s-IgA concentration and secretion rate to be lower on days with high levels of positive affect.

Using a between-subjects analysis in their study of 114 nurses, Graham and colleagues (1988) found that

nurses who reported that they were frequently anxious had lower secretion rates of s-IgA than nurses who reported that they were "occasionally" anxious, but no differences in s-IgA concentrations were observed. Both s-IgA concentration and secretion rate were unrelated to depression, as measured by one item ("How often do you feel depressed?"), and to psychological distress, as measured by the health questionnaire (Goldberg, 1972). It is possible that the anxiety-associated reductions in IgA secretion rates were due to the rate of saliva flow, which is under autonomic control, rather than to direct influence on the s-IgA secretion rate.

In the study by Green and colleagues (1988), reviewed above, no relation was observed between s-IgA concentration and subjective distress as measured with the Hopkins Symptom Checklist (Derogatis *et al.*, 1974). Kugler *et al.* (1992) collected saliva and administered a mood adjective checklist to 84 medical students. Of the 15 dimensions on their adjective checklist, only "excitement" was positively related to s-IgA concentration.

SUMMARY

Although relatively few studies have examined the relation between subjective distress and s-IgA, the above studies suggest that in order to understand the influence of the psychosocial environment on s-IgA, future researchers should include measures of affect and subjective distress in their study design. The findings by Stone *et al.* (1987a, 1996)—that both negative and positive affects mediated the relation between daily events and s-IgA antibody production—indicate that researchers should not only focus on the role of negative affect but should also consider the contribution of positive affect.

With the exception of the daily assessment studies, the above studies assessed psychological distress or affect at one point in time, and it was not clear what time frame was used. The reliability of subject recall is an issue in those studies that may have used a long time frame.

Conclusion and Future Directions

It is clear that there is substantial evidence that psychosocial variables can affect secretory immunoglobulin A. It should also be evident that it is difficult to compare and draw definite conclusions from these studies, since they differed in several key variables, including the duration and type of the stressors and interventions, timing of assessments relative to the stressors and interventions, and methods used to assay secretory IgA. The majority of the reviewed studies assessed concentrations of s-IgA without controlling for the amount of saliva collected during the sampling period. Therefore, the possibility that the stress-elicited changes in s-IgA concentration were due to stress-induced changes in flow rate cannot be ruled out. Secretory IgA secretion rate was assessed in some of the above studies, and in some

instances, opposite patterns were observed for s-IgA secretion rate and s-IgA concentration. For example, McClelland *et al.* (1985) found that an examination stress increased s-IgA concentration, whereas Jemmott *et al.* (1983) found that the same stressor decreased s-IgA secretion rate. Herbert and Cohen (1993), in their meta-analytic review, compared the results of studies that reported the concentration of s-IgA with those that reported the secretion rate. Their analysis showed that the association between stress and s-IgA concentration was significantly stronger than the association between stress and s-IgA secretion rate. Until more studies have demonstrated that psychosocial factors affect s-IgA after controlling for salivary flow rate, results of s-IgA concentration have to be interpreted cautiously.

Studies that examined the relation between stressful events and s-IgA support the hypothesis that events are associated with reduced s-IgA. However, since all of these studies were correlational, they do not address the issue of causality. The clinical significance of these stress-elicited changes in s-IgA is not yet known, and these alterations may reflect transient fluctuations within the range of normal function. Some investigators assessed whether subjects had been sick in the months preceding their participation in the studies. McClelland and colleagues (1980, 1982) found some evidence that subjects who were high in need for power and high on power-related stress had lower levels of s-IgA concentrations and reported more illnesses in the previous 12 months than other subjects. On the other hand, Graham *et al.* (1988) found no relation between s-IgA secretion rate and upper respiratory infection in the past 12 months. One difficulty with interpreting these findings is that it is not clear if subjects were sick at the time that their saliva was collected for immune assessments, which could affect s-IgA concentrations and secretion rate.

Stone and colleagues found (Stone *et al.*, 1987a, 1994) that stress interfered with the production of antibody responses to a novel antigen. These findings indirectly support the hypothesis that stress-induced changes in s-IgA may have clinical significance, since the responses to the novel antigen may be analogous to those that would occur if the individual were exposed to a virus or a bacterium. Clearly, longitudinal and experimental studies are needed for further examination of the clinical impact of stress-induced changes in s-IgA.

The mechanism whereby stress affects s-IgA is not clear. It has been hypothesized that stress affects the activity of the immune system through its impact on the hypothalamic-pituitary-adrenal axis and the sympathetic nervous system. Several studies have demonstrated that these pathways are activated by stress, which results in increased levels of circulating catecholamine and cortisol. There is also accumulating evidence indicating that the immune cells have receptors for these hormones, which

supports the hypothesis that they are involved in immune modulation (see review by Rabin *et al.*, 1989; O'Leary, 1990; Ader *et al.*, 1991; Ader and Felten, 1995; Weigent and Blalock, 1995; Bedovsky and Rey, 1996). Some of the studies reviewed above did assess catecholamine (McClelland *et al.*, 1985; Kugler *et al.*, 1992, 1993) and cortisol (Evans *et al.*, 1994). Although changes in these hormones were observed in parallel to changes in s-IgA, it is not clear if these hormonal changes accounted for or contributed to the stress-induced changes in s-IgA, since the investigators either found no relation between their hormonal measures and their measures of s-IgA or did not examine whether the immune changes were due to the hormonal changes. That is, mediational models of the observed relations were not tested. Thus, whether stress affects the activity of s-IgA through its impact on neuroendocrine pathways has not been answered.

There is some evidence that psychological distress mediates the relation between stress and s-IgA. Stone and colleagues (1996) found that increases in negative mood mediated the negative relation between undesirable events and s-IgA antibody production, and that increases in positive mood mediated the positive relation between undesirable events and s-IgA antibody production. It is possible that behavioral responses account for the immune changes found in these studies. There is evidence that health practices—such as smoking, amount of sleep, and alcohol consumption—can affect the activity of the immune system (MacGregor, 1986; Irvin *et al.*, 1992), including s-IgA (Bennet and Reade, 1982). Until additional studies are conducted that control for these health practices, the possibility that the stress-induced changes in s-IgA were due to changes in health practice cannot be ruled out.

The literature on the effects of psychobehavioral intervention on s-IgA is promising but preliminary. These studies tested various intervention techniques, and short-term increases in s-IgA were observed. It is not clear how long these changes persist, and it is not yet known whether these interventions will buffer the effects of stress on s-IgA, since none of the studies exposed subjects to stress after they had undergone the intervention. The clinical significance of these changes is also not known. The only study that assessed number of symptoms (Rider *et al.*, 1990) found that subjects who were trained in relaxation had higher levels of s-IgA and reported fewer symptoms during the study; however, the particular symptoms affected were not immune-related (breathing difficulty, jaw clenching, and rapid heartbeat).

It is not clear through which mechanism these interventions affected s-IgA. These interventions presumably reduce subjective distress and physiological arousal. Only two studies included neuroendocrine assessments (Green and Green, 1987; Jasnoski and Kugler, 1987), and both studies reported that there was no change in these

measures following the intervention. Surprisingly, of the three studies (Green *et al.*, 1988; Rider *et al.*, 1990; Groer *et al.*, 1994) that assessed psychological distress, only one study (Rider *et al.*, 1990) observed a decrease in psychological distress after the intervention. Systematic investigations of the mechanisms underlying the effects of psychosocial interventions on s-IgA are needed, since those studies will provide information about both the clinical significance of psychosocial interventions and the possible primary and secondary mechanisms underlying the relation between stress and s-IgA.

It is clear that there has been a considerable effort to understand how the psychosocial environment affects s-IgA. While the majority of studies support an association, several issues concerning this literature remain problematic and should be the object of future research. Results are not consistent among studies using s-IgA concentration and secretion rates as outcomes. The resolution of these issues may lie in the proper measurements of salivary flow. Questions have been raised about the meaning of total s-IgA assessments, and empirical work is needed for the health consequences of total and/or specific measures of s-IgA to be shown convincingly. Psychologic and physiologic pathways translating environmental events into changes in s-IgA also need to be systematically investigated.

POSITIVE AND NEGATIVE MOOD: ASSOCIATION WITH NATURAL KILLER CELL ACTIVITY

HEIDDIS B. VALDIMARSDOTTIR and DANA H. BOVBJERG

*Memorial Sloan-Kettering Cancer Center, Cornell University Medical College,
New York, NY 10021*

(Received 13 November, 1995; in final form 12 December, 1995)

Negative mood (e.g., emotional distress) is known to affect immune function, but little research has addressed effects of positive mood. In the present study, positive and negative mood (over a day) were examined for their relations to natural killer cell activity (NKCA) in 48 healthy women. Results indicated that women reporting some negative mood ($N = 26$) had lower levels of NKCA than women who had no negative mood, while those with higher levels of positive mood had higher NKCA. However, as indicated by the significant interaction between positive and negative mood, the relation between positive mood and NKCA depended upon the women's experience of negative mood. Higher levels of positive mood were related to higher levels of NKCA only among the women who reported having some negative mood over the day. These results raise the possibility that positive mood may moderate, or buffer, the effects of negative mood on immune function.

KEY WORDS: Psychoneuroimmunology, positive mood, negative mood, natural killer cell activity.

INTRODUCTION

Individuals undergoing stressful life events have been found to have a higher incidence of a variety of illnesses that suggest immune system involvement (Brown and Harris, 1989; Holmes and David, 1989). As recently confirmed in a meta-analytic review (Herbert and Cohen, 1993) studies have consistently found altered immune function in individuals encountering various distressing life events including: loss of a spouse or loved one, divorce or marital separation, unemployment, taking care of a sick relative, and taking academic examinations. There is also evidence that undesirable day-to-day events (e.g., argument with spouse) can affect immune function (Stone, Neale, Cox, Napoli, Valdimarsdottir, and Kennedy-Moore, 1994; Stone, Marco, Cruise, Cox, and Neale, 1995). The possible effects of positive life events on immune function have received less research attention, but initial evidence suggests an association. For example, Stone and colleagues (1994) found that individuals reporting more desirable daily events (e.g., close interaction with spouse) had stronger salivary antibody responses (sIgA) to oral challenges with a novel antigen.

It has been hypothesized that the relations between life events (positive or negative) and alterations in immune function are mediated by changes in affective states which, in turn, lead to changes in neuroendocrine pathways and/or in health related behaviors

Correspondence to: Dr. Heiddis B. Valdimarsdottir, Department of Psychiatry, Memorial Sloan-Kettering Cancer Center, 1275 York Avenue, New York, New York, 10021 USA, Tel: (212) 639-3279, E-mail: Heiddis@neuro.MSKCC.org.

(Cohen, Kessler, and Gordon, 1995). Supporting the hypothesized role of negative affective states, Stone and colleagues (1995) reported that increases in negative mood mediated the relation between undesirable daily events and lower antibody responses to an oral antigenic challenge. Several other studies have shown that negative affective states are associated with alterations in various immune parameters, including: reductions in natural killer cell activity (Irwin, Daniels, Bloom, Smith, and Weiner, 1987; Bovbjerg and Valdimarsdottir, 1993); reduced lymphocyte proliferative responses (Linn, Linn, and Jensen, 1981); lower serum antibody responses to Hepatitis B vaccine (Jabaaij, Grosheide, Heijtkink, Duivenvoorden, Ballieux, and Vingerhoets, 1993); and reduced salivary antibody responses to oral challenges with a novel antigen (Stone, Cox, Valdimarsdottir, Jandorf and Neale, 1987).

On the other hand, relatively little research has addressed the possible influence of positive affective states on immune function. Stone and colleagues have reported that increases in positive mood mediated the relation between desirable daily events and salivary antibody responses to antigenic challenge (Stone *et al.*, 1995). Relations between higher levels of positive mood and higher salivary antibody responses to antigenic challenges were also reported in two previous studies by this group (Stone *et al.*, 1987; 1994).

These studies on salivary antibody responses to oral antigenic challenges raise the possibility that positive and negative mood may have differential effects on immune function. However, it is not clear if immune measures besides salivary antibody responses are similarly affected. The present study focused on the possibility that NKCA may be differentially affected by positive and negative mood. Considerable evidence indicates that NKCA is particularly sensitive to emotional distress (O'Leary, 1990) but little research attention has been paid to the possible effects of positive mood on NKCA.

Consistent with previous naturalistic studies, we hypothesized that negative mood would be associated with lower levels of NKCA, while positive mood might prove to be associated with higher levels of NKCA. We also explored the possibility that positive mood might reduce the effects of negative mood on NKCA, as some researchers have suggested that positive emotions may serve as a stress buffer (Edwards and Cooper, 1988).

METHOD

Subjects

Women were recruited by announcements posted in staff areas of three contiguous medical centers. Participants ($N = 48$) reported having no chronic medical condition, no current use of medication and no symptoms of infectious disease in the last three days. The mean age was 38.8 years (range 22–63). The majority of the women were white (71%), single (71%), employed (85%), well educated (72% had attended college), and premenopausal (81%).

Procedure

Subjects were scheduled to come to the laboratory at the same time of day on two consecutive days. On the first day, basic demographic data were collected and subjects completed psychobehavioral questionnaires (see below). Blood was then collected for

assessment of NKCA (see below), conducted by a technician blind to the results of the questionnaires. On the second day of assessment, subjects again completed the psychobehavioral questionnaires and blood samples were collected.

Assessments

Demographic information was collected on a standard questionnaire to obtain information on age, race/ethnicity, and marital status (Bovbjerg and Valdimarsdottir, 1993).

Positive and negative affect was assessed, on both assessment days, using a questionnaire developed by Guadagnoli and Mor (1989). This questionnaire has 2 scales, positive and negative affect, which were derived from principal component analyses of the 65 mood adjectives in the Profile of Mood States (McNair, Lorr, and Droppleman, 1971). The two scales (positive and negative affect) each consist of 7 adjectives scored from 0 (not at all) to 4 (extremely), with results reported as the mean of all 7 items. In two independent samples of subjects, these investigators found that the scales for positive and negative mood had high alpha coefficients ($> .70$) and were independent of each other. We confirmed these high alpha coefficients ($> .90$) within each scale in the present sample, but found that the scales were inversely correlated ($r = -.49$, $p < .01$). Because of the high test-retest correlations across the two assessment days (p 's $< .01$), the mean of each scale for the two days was computed and used in all subsequent analyses. It should be noted that during the course of the study the timeframe of the questionnaire was modified from "this week including today" ($N = 20$) to "today" ($N = 28$), reflecting considerations relevant to our ongoing research program. To ensure that this modification did not influence the results presented here, we entered this grouping variable as a covariate into the analyses described below; including this covariate did not alter any of the results.

Daily Habits (e.g., alcohol consumption) that may be influenced by affective states, and which could in turn influence immune function (Kiecolt-Glaser and Glaser, 1988), were assessed with a standard questionnaire (Bovbjerg and Valdimarsdottir, 1993). This questionnaire uses a self report format to assess: sleep, eating patterns, cigarette smoking, alcohol consumption, use of licit and illicit drugs, as well as infectious disease symptomatology, over the three days prior to the blood collection.

Complete blood counts (CBC) with differential were performed by a commercial laboratory (Methpath, Teterboro, NJ). Because of the high test-retest correlations across the two days of assessment (p 's $< .004$) mean counts were computed and used in all subsequent analyses.

Natural Killer Cell Activity (NKCA) was assessed, on both assessment days, using peripheral blood mononuclear cells, isolated from heparinized blood samples by standard Ficoll-Hypaque gradient centrifugation (Bovbjerg and Valdimarsdottir, 1993). Cytotoxic activity against the classic NK-sensitive K562 tumor cell line was assessed in a standard ^{51}Cr release assay at three different effector to target cell ratios (10:1, 30:1 and 100:1), as previously described (Bovbjerg and Redd, 1992). Data from all effector to target cell ratios were included in the statistical analyses, as a more conservative approach than use of summary values such as mean cytotoxic activity or lytic units (Pollock, Zimmerman, and Fuchshuber, 1990). Because of the high test-retest correlations across the two days of assessment (p 's $< .01$) the mean at each E:T cell ratio was computed and used in all subsequent analyses. It should be noted that repeated

measures ANOVA revealed no significant (p 's $> .25$) differences (main effect of Time or interactions with Time) in NKCA between the two days of assessment.

RESULTS

Positive and negative mood

The mean level of negative mood in the study sample was 0.42 ± 0.90 (SD). Consistent with previous studies (Watson and Tellegen, 1985) the negative mood scores were highly skewed towards the low end (22 of the 48 subjects had negative mood scores of zero across the two days of assessment); in the subgroup of women with some negative mood the mean level of negative mood was 0.79 ± 1.10 . The mean level of positive mood was 2.30 ± 0.85 . Again consistent with previous studies (Watson and Tellegen, 1985), the positive mood scores were approximately normally distributed. Because of these different distributions, negative mood was treated as a dichotomous variable (women with some negative mood vs women with no negative mood) and positive mood was treated as a continuous variable in all subsequent analyses. The mean level of positive mood was 1.97 ± 0.65 in the subgroup of women with some negative mood, and 2.70 ± 0.91 in the subgroup of women with no negative mood.

Association between NKCA and affective states

The mean levels of NKCA in the study sample at the three effector to target cell ratios were: 19.5 ± 11.6 (10:1), 35.5 ± 15.7 (30:1), 53.1 ± 15.7 (100:1). The hypothesis that negative and positive mood would be differentially associated with NKCA was examined with multivariate regression analyses (using SAS General Linear Model), entering positive and negative mood as predictors. The possible role of positive mood as a stress buffer was examined by including the interaction term (positive \times negative mood) in the analyses; including the interaction was all the more important because of the inverse correlation found between the mood scales (see Methods). The results indicated that positive mood was associated with higher levels of NKCA ($F(1,44) = 10.01$, $p = .002$) and negative mood was associated with lower levels of NKCA ($F(1,44) = 7.35$, $p = .009$) mood. The interaction between positive mood and negative mood was also significant ($F(1,44) = 8.05$, $p = .007$) across the three effector to target cell ratios. No significant relations were seen with the complete blood count data (i.e., numbers of white cells, lymphocytes, monocytes, or polymorphonuclear cells).

To determine the source of the significant interaction for NKCA, we examined the relations between positive mood and NKCA within the subgroups of women who reported no negative mood across the two days of assessment ($N = 22$) and those reporting some negative mood ($N = 26$). We first examined the relations between positive mood and NKCA in the subgroup of women who reported no negative mood. Regression with repeated measures revealed no significant main effect of positive mood ($F(1,20) = .06$, $p = .80$) or interactions with effector to target cell ratios (p 's $> .2$). Higher levels of positive mood were not associated with higher levels of NKCA in the subgroup of women who reported no negative mood, as is graphically represented (at the 100:1 effector to target cell ratio) by the flat regression line in the Figure. A similar pattern of response was seen at the other two effector to target cell ratios (not shown).

Figure 1 Relations between positive mood and natural killer cell activity in the subgroups of women who reported having some negative mood (solid line) and those who reported no negative mood over the two assessment days (dotted line).

On the other hand, there was a relation between positive mood and NKCA in the subgroup of women who reported some negative mood across the two days of assessment. Regression with repeated measures revealed a main effect of positive mood ($F(1,24) = 16.86$, $p < .001$), which accounted for 41% of the variance in NKCA; no significant interactions with effector to target cell ratios (p 's $> .2$) were observed. Higher levels of positive mood were associated with higher levels of NKCA in the subgroup of women who reported some negative mood, as is graphically represented (at the 100:1 effector to target cell ratio) by the upward slope of the regression line in the Figure. A similar pattern of response was seen at the other two effector to target cell ratios (not shown).

Because there was variability in the intensity of negative mood within this subgroup of women reporting some negative mood over the assessment days, it was possible that variability in negative mood could have contributed to the relation between positive mood and NKCA. To examine this possibility, we entered negative mood as a covariate into the analysis described above; positive mood remained a significant predictor of NKCA across the three effector to target cell ratios ($F(1,23) = 15.92$, $p < .001$); again there were no significant interactions with effector to target cell ratio. We also considered the possibility that the subgroup of women who reported some negative mood may have had more variability in positive mood, which could provide an alternative explanation for why we only found a relation between positive mood and NKCA in the subset of women reporting some negative mood, but no such differences were found between the groups.

Do differences in demographic variables and/or daily habits account for the relations between NKCA and affective states?

To examine the possibility that individual differences in demographic variables or daily habits (e.g., amount of sleep) may have accounted for the results presented above, we examined the relations between these variables and NKCA in this sample, using repeated measures ANOVA for each variable (with effector to target cell ratio as a within-subject factor). The results revealed no significant main effects (p 's $> .2$) on NKCA for any of the demographic variables, menopausal status, or daily habits and no significant interactions with target cell ratio.

DISCUSSION

The results of the present study revealed that women reporting some negative mood had lower levels of natural killer cell activity (NKCA) than women who had no negative mood over the two assessment days, while those with higher levels of positive mood had higher NKCA. However, as indicated by the significant interaction between positive and negative mood, the relation between positive mood and NKCA depended upon the women's experiences of negative mood. Higher levels of positive mood were related to higher levels of NKCA only among the women who reported having some negative mood over the days. Inspection of the Figure suggests that, within this subgroup of women, higher levels of positive mood are associated with higher levels of NKCA, which approach those of women who did not report any negative mood over the two days of assessment. These results raise the possibility that positive mood may moderate, or buffer, the effects of negative mood on immune function.

The possibility that positive emotions may serve as a stress buffer has been suggested by several investigators (Edwards and Cooper, 1988; Lazarus, 1991; Lazarus, Kanner, and Folkman, 1980). For example, Lazarus and colleagues (1980; 1991) have articulated three possible means by which positive emotions may serve as buffers. Positive emotions may: 1) enhance coping by providing a "breather" from ongoing stress; 2) help to sustain ongoing coping needed to resolve a challenge; or, 3) restore psychological resources depleted by stress. Empirical support for the stress buffering effects of positive mood is scant. Consistent with the hypothesis, Cohen and Hoberman (1983) have reported that the number of positive events experienced by an individual moderated the relation between negative life-events and depressive/physical symptomatology. Similarly, Reich and Zautra (1981) found that engaging in pleasant activities reduced distress only for individuals who also reported high levels of life stress.

To our knowledge, the present study is the first to consider the possible role of positive mood as a buffer, interacting with the effects of negative mood, on measures of immune function. Previous studies of affective states and immune function have focused on the direct effects of positive and negative mood. For example, Stone and colleagues (1987, 1984) found that negative mood was associated with smaller antibody responses to challenge antigen, while positive mood was associated with larger antibody responses. These studies, however, did not examine possible interactions, making comparisons to the results of present study problematic.

It is also difficult to compare the results of the present study to those of two recent studies in which positive and negative moods were experimentally induced (Knapp, Levy, Giorgianni, Black, and Fox, 1992; Futterman, Kemeny, Shapiro, and Fahey, 1994).

Knapp and colleagues (1992) found no significant changes in NKCA following the induction of maximally disturbing or maximally pleasurable emotional experiences. Futterman and colleagues (1994) found transient increases in the levels of NKCA following the induction of either positive or negative mood states by "method" acting techniques. Neither of these studies was designed to examine the possible buffering effect of positive mood. It would be of interest in future studies to experimentally test the buffering effects of positive mood, perhaps following methods analogous to those of Gerin and colleagues, who have recently experimentally demonstrated the buffering effects of social support on cardiovascular reactivity (Gerin, Milner, Chawla, and Pickering, 1995).

The results of the present naturalistic study should be interpreted cautiously for several reasons. First, the study sample was relatively modest in size and was restricted to women. Second, the study measure of mood was limited to the scale developed from the POMS by Guadagnoli and Mor (1989). This scale has not been widely used; and the negative mood scale may suffer from floor effects, as 22 subjects had no negative mood on two consecutive days. Third, the immune assessments in the study were limited to CBC with differential count and NKCA; generalizability to other aspects of immune function cannot be assumed. Fourth, we cannot rule out the possibility that the observed relations between mood and NKCA may have been secondary to a number of unassessed psychosocial mediating variables. For example, individuals with more social support have been reported to have higher levels of positive mood (Cohen and Wills, 1985), and independent studies have found that social support is associated with higher NKCA (Baron, Cutrona, Hicklin, Russell, and Lubaroff, 1990). Positive mood may also be related to humor, which has been reported to have effects on immune function (Lefcourt, Davidson-Katz, and Kueneman, 1990; Edwards and Cooper, 1988; Martin and Dobbin, 1988; Dillon, Minchoff, and Baker, 1985). Fifth, differences in positive and negative emotions may reflect underlying personality differences. For example, several studies have found that negative mood is strongly related to neuroticism whereas positive mood is related to extraversion (Costa and McCrae, 1980). Based on the present results, further research with a larger sample of both men and women, with additional measures, assessed at multiple time points is clearly warranted. The initial evidence from the present study, consistent with the buffering hypothesis of positive mood, highlights the importance of further research in this area.

It remains to be determined whether the influence of positive mood on immune function will predominantly be due to effects on putative neuroendocrine pathways, which may affect either the number of NK cells in circulation or the functional activity of each cell (Whiteside and Herberman, 1994). Alternatively, the effects of positive mood on NKCA may be due to more indirect influences having an impact on coping mechanisms (Brown, Sirota, Niaura, and Engebretson, 1993; Edwards and Cooper, 1988). Regardless of the mechanisms responsible, the present study suggests that the assessment of positive mood may make an important contribution to future studies of psychological influences on immune function. As natural killer cells are thought to play an important role in cancer as well as in defense against infectious disease (Biron, 1994; Whiteside and Herberman, 1994), it will be important for future research to examine the possibility that these influences of mood may have clinical significance.

ABSTRACT

Having a family history of cancer is an important predictor of lifetime cancer risk. Individuals with family histories of cancer have been reported to experience symptoms of general distress and to have frequent intrusive thoughts and avoidance regarding cancer. To date, little is known about predictors of such distress. A relation between perception of cancer risk and distress has been suggested, but the possibility that prior cancer-related events may contribute to distress in these women has received little attention. The major aim of the study was to examine the contribution of the past experience of the death of a parent from cancer to distress in women at familiar risk for breast cancer.

Women with family histories of breast cancer (Risk Group, N = 46) were assessed on the day of their yearly mammography screening and four to eight weeks after normal result notification in order to confirm the generalizability of their distress. Their levels of intrusive thoughts, avoidance, and perceived lifetime risk for breast cancer were significantly higher than those of women with no family histories of cancer who were not undergoing mammography (Comparison Group, N = 43), and this was true on both assessment days. Among the women in the Risk Group, those whose parent(s) had died of cancer had the highest levels of intrusive thoughts, avoidance, and perceived risk. Results sug-

gested that perceived risk mediated the effect of this event on intrusive thoughts and avoidance regarding breast cancer. The findings are discussed in terms of theories of cognitive responses to traumatic and stressful life events. Implications for future research and interventions are discussed.

(Ann Behav Med 1997, 19(4):362-369)

INTRODUCTION

Having a family history of cancer is a significant risk factor for developing cancer in one's lifetime (1). Several recent studies, although not all (2), have shown that having a family history of cancer, including breast cancer, may be associated with elevated levels of distress (3-5). For example, Valdimarsdottir et al. (5) compared women with and without family histories of breast cancer. Those who had family histories of breast cancer had significantly higher levels of intrusive thoughts and avoidance on the Impact of Events Scale (IES) (6), as well as higher levels of general distress, anxiety, phobic anxiety, somatization, and depression on the Brief Symptom Inventory (BSI). Kash et al. (3) found that 27% of women with family histories of breast cancer endorsed levels of distress on the BSI that suggested a need for psychological counselling. In a study by Lerman et al. (4), women with family histories of breast cancer reported levels of intrusive thoughts that were comparable to those found in clinical populations. In 30% of these women, worries about breast cancer interfered with their daily lives. Preliminary data also suggested that women with family histories of cancer may have mood disturbances comparable to those seen in patients recently diagnosed with breast cancer (7).

Despite the accumulating evidence that women with family histories of cancer have higher levels of distress, it is clear that not all of these women are equally affected. While some women may have reactions severe enough to warrant clinical attention (3,4), others have less severe stress symptoms. To date, little is known about the predictors of distress in women with family histories of cancer, as only a few studies have addressed this issue. Schwartz et al. (8) showed a relation between perceived risk for cancer and intrusive thoughts, as well as an indirect relation between a monitoring coping style and intrusive thoughts. Lerman, Kash, and

Stefanek (9) suggested that a woman's current age may be associated with her level of distress. Wellish et al. (10) reported that a woman's age at the time of her mother's breast cancer diagnosis was associated with distress levels, in that those who were adolescents at the time appeared to have the greatest adjustment problems.

Yet to be considered is the impact of past cancer-related events, chief among which is likely to be a parent's death from cancer. The loss of a parent from cancer, which may be preceded by a long and painful decline in the parent's health and which can entail long-term care-giving needs provided by close family members, is an event that seems likely to contribute to chronic stress, especially when the bereaved perceive themselves at risk for the disease and may live in fear of meeting the same fate. Consistent with this hypothesis, research on the psychological effects of experiencing the death of a parent to any cause has shown that this life event has profound psychological consequences including distress, intrusive thoughts, and avoidance (11-16). In addition to symptoms of distress, a feeling of vulnerability (or perceived risk) which may be triggered by stressful or traumatic events including a parent's death (16,17) is an important response to take into consideration as it appears to play an important role in women with family histories of cancer (18). Perceived risk for developing cancer has been shown to be associated with distress in these women (8).

The principal aim of the present longitudinal study was to examine the contribution of a past experience of parental loss to cancer to distress in women who are at familial risk for breast cancer. To address this aim, we first sought to replicate previous findings by Valdimarsdottir et al. (5), which indicated that women with family histories of breast cancer have higher levels of distress, including intrusive thoughts and avoidance about breast cancer as well as more general distress, compared to women without cancer in their families. Since that study and others have shown that distress about cancer may be more prominent in women with family histories of cancer when specific cancer cues (e.g. mammography) are present (5,19), we assessed distress twice in this group: once on a day of mammography and once four to eight weeks after notification of normal mammography results. As in our previous study (5), women without family histories of cancer were concurrently assessed on two occasions without mammography to provide an indication of distress levels in the community and to control for the effects of two assessments per se. We then extended the previous findings by examining the contribution of having experienced a parent's death from cancer to the elevated levels of distress (general distress as well as intrusive thoughts and avoidance regarding breast cancer) and perceived risk reported by women with family histories of breast cancer. For this purpose, women with family histories of breast cancer were divided into two subgroups: those whose parent(s) had died from cancer and those whose parents had not died from cancer. These subgroups were then compared to the group of women without family histories of cancer. Finally, among the women with family histories of cancer, we then further explored predictors of their distress. Based on previous research on bereaved individuals, as well as women at risk for cancer (8,16), we hypothesized that a greater sense of personal vulnerability to developing breast cancer (i.e. perceived risk) in the women whose parent(s) had died of cancer may account for the higher levels of distress in these women. Our repeated measures design allowed us to explore whether these relations were more prominent on a day when cancer-related cues are present (Assessment Day 1) compared to a day without such a

cue, four to eight weeks after receiving the news of normal mammography results (Assessment Day 2).

METHOD

Subjects

The study included a total of 89 women who were participating in a broader longitudinal study examining the psychobiological effects of mammography screening in women at familial risk for breast cancer. All subjects who were recruited after we revised our family history questionnaire to obtain data necessary to address the present hypotheses (e.g. cause of parent's death) were included in this study. Of those, 46 women with at least one first-degree relative (mother, sister, daughter) who had previously been diagnosed with breast cancer (Risk Group) were recruited from three cancer screening programs in New York City prior to a routine mammography screening. The remaining 43 women had no cancer history in their first-degree relatives (Comparison Group) and were recruited through advertisements in the community.³ Eligible subjects had no personal history of neoplasm or chronic disease, no prior abnormal mammograms or biopsies, and no current chronic mental or physical illness and were not taking medication on a regular basis. Women whose first-degree relatives were currently under active cancer treatment were excluded from the study. Subjects' ages ranged from 22.8 to 54.6 ($M = 41.6$, $SD = 6.8$), the majority of subjects were Caucasian, married, and employed and had at least some college education.

For some of the analyses, subjects in the Risk Group were split into two subgroups based on whether or not they had experienced the death of a parent from cancer. Risk Subgroup 1 consisted of the subjects who had at least one parent who had died of cancer ($N = 30$; mother died: $N = 18$, father died: $N = 5$, both parents died: $N = 7$), and Risk Subgroup 2 included those whose parents had not died of cancer ($N = 16$). The cause of death of all the deceased mothers in Risk Subgroup 1 was breast cancer. It should be noted that some of the women in the Risk Group had more than one first-degree relative who was diagnosed with cancer. This variable (number of first-degree relatives with cancer) was therefore included in the initial statistical analyses assessing subgroup comparability.

Procedures

Women with family histories of breast cancer (Risk Group) were recruited by telephone approximately one week before a scheduled routine mammography screening for breast cancer. They were first assessed in the clinic prior to mammography (Assessment Day 1) and then assessed again four to eight weeks later (Assessment Day 2). On Assessment Day 1, subjects completed several questionnaires including a family history questionnaire, demographics, a perceived risk scale, the Brief Symptom Inventory (20) assessing general distress, and the Impact of Events Scale (6) assessing intrusive thoughts and avoidance regarding breast cancer. They also underwent mammography screening and were informed of their results.³ None of the women had abnormal mammography results. On Assessment Day 2, subjects again completed the BSI, the IES, and the perceived risk scale in the absence of mammography screening. Women without family histories of breast cancer (Comparison Group) were scheduled for concurrent research assessments with the Risk Group but were not scheduled for mammography. This group was included in this study in order to provide comparison data from a healthy community sample that had not experienced cancer in first-degree relatives, allowing us to control for the stress of daily living in an

urban community and to examine the effects of two assessments per se.

Measures

Demographic Questionnaire: Subjects completed a standard questionnaire asking about their age, race, education, income, and marital status (5).

Family History of Cancer: This questionnaire was designed to assess the occurrence of cancer in subjects' biological relatives as well as other variables related to the cancer diagnosis, including age of the patient at time of diagnosis, survival status, and age of the subject at the time of the relatives' diagnosis and death (if applicable). Lifetime objective risk was calculated based on the Claus and the Gail models (21,22). Both models were included in this study because they use different variables to calculate risk (and often yield different risk scores) and have both been used in previous studies of breast cancer risk (1). The Claus model takes into account the number of affected first- and second-degree relatives and age of relatives at time of diagnosis (22). The Gail model takes into account the number of affected first-degree relatives, age at first live birth, age of menarche, number of benign breast biopsies, and history of breast biopsies with hyperplasia (21).

Perceived Risk for Breast Cancer: Subjects rated their perceived likelihood of developing breast cancer in their lifetime from 0 (not at all likely) to 100 (extremely likely) (5). This measure was administered at both assessment days. Because results from the two assessment days were highly correlated ($r = .85, p < .0001$) and the perceived risk scores obtained at the two assessments did not differ significantly, the combined mean of the two scores was used for subsequent statistical analyses.

Brief Symptom Inventory: The BSI (20) was administered on both Assessment Days as a measure of general distress. The BSI includes nine subscales based on separate symptom dimensions (somatization, obsessive-compulsive, interpersonal sensitivity, depression, anxiety, hostility, phobic anxiety, paranoid ideation, and psychoticism) and one general score, the General Severity Index (GSI). The BSI was selected because it has been used in previous studies of distress in women at familial risk for breast cancer (3,5). Subjects indicated on a scale from 0 (not at all) to 4 (extremely) how much discomfort each of the symptoms had caused them "in the past week including today."

Impact of Events Scale: This questionnaire (6) assesses the frequency of intrusive thoughts and avoidance with regard to a specific stressor. The specific stressor chosen for the IES was breast cancer. The IES consists of 15 items, including 7 items for the Intrusion subscale and 8 items for the Avoidance subscale. This measure was chosen because it assesses symptoms reflective of current distress (6) and because it has been used in studies of responses to parental death (13) as well as studies of cancer-specific distress in women at familial risk for cancer (5,8). Subjects were asked to rate how frequently each thought or behavior occurred "during the past week including today."

Statistical Analyses

Analyses of variance (ANOVA) and chi-square analyses were first conducted to test possible group differences in demographic variables. Any variable that was found to differ among the groups and was correlated ($p < .1$) with the dependent variables was

Age (years)	45.0 (4.6) ^a	40.6 (4.8) ^b	39.7 (9.9) ^b
Education (college grad)	76.7% ^a	81.3% ^a	81.4% ^a
Ethnic group (White)	93.3% ^a	87.5% ^a	72.1% ^a
Marital status (married)	76.7% ^a	62.5% ^{ab}	34.9% ^b

Groups with same superscript are not significantly different ($p > .10$).

included as a covariate in subsequent analyses. Repeated measures analysis of covariance (ANCOVA) was then used to examine differences between the Risk Group and the Comparison Group in distress (BSI, IES) on the two Assessment Days, and in perceived risk. In the second phase of the analysis, the Risk Group was divided into two Risk Subgroups according to the women's experience of a parental death from cancer. In addition to assessing general demographic variables, we also examined factors associated with the cancer diagnosis in the two Risk Subgroups,⁴ including the number of affected first-degree relatives, their age at time of diagnosis, the subject's age then, the recency of diagnosis, and the subject's objective risk (Claus and Gail models). We applied the same rule for including covariates as we did in the analyses described above. A similar repeated measures ANCOVA then compared these two Risk Subgroups with the Comparison Group on the same dependent measures. Post-hoc analyses were done using the Duncan test with an alpha level set at .05. The third phase of the analysis consisted of a series of regression analyses examining the possible role of perceived risk as a mediator of the associations between the Risk Subgroups and intrusive thoughts and avoidance. Whenever there was no significant Assessment Day by Group interaction, Beta weights and r^2 values were calculated using the mean of IES scores across the two Assessment Days in regression analyses.

Finally, additional analyses were conducted to examine potential associations of variables related to the parent's cancer death with the subject's distress and perceived risk. This was done to explore possible mechanisms for the association between the experience of a parent's death from cancer and distress in order to provide suggestions for future research.

RESULTS

Group and Subgroup Comparability

The Risk and Comparison Groups were significantly different on two of the demographic variables: marital status and subject's current age, $X^2(88) = 12.15, p < .001$, and $F(1,87) = 5.12, p < .03$, respectively (see Table 1). Since these variables were significantly related with distress and perceived risk ($p < .1$), we included age and marital status as covariates in all the analyses comparing the Risk Group with the Comparison Group. No significant differences were seen for any other demographic variables.

We also compared demographic and diagnosis-related variables between the two Risk Subgroups. There was a significant difference for the subject's current age, for recency of the affected relative's diagnosis, and the subject's age at the time of diagnosis, $F(1,45) = 9.36, p < .01$; $F(1,44) = 17.14, p < .01$; and $F(1,44) = 3.99, p = .05$, respectively (see Table 2). In addition, there was a marginally significant difference for the number of first-degree relatives diagnosed with cancer, $X^2(45) = 3.49, p = .062$ (see

TABLE 2
Cancer-Related Variables and Objective Risk for Breast Cancer

	Risk Subgroup 1 Mean (SD), Range	Risk Subgroup 2 Mean (SD), Range
Objective risk for breast cancer:		
-Claus Model	20.9 (10.5) ^a , 8.8–46.0	18.2 (8.0) ^a , 8.8–35.4
-Gail Model	17.2 (4.3) ^a , 12.0–31.4	18.4 (4.5) ^a , 15.0–27.8
Subjects with more than one affected first-degree relative	46.7% ^a	18.8% ^b
Cancer diagnosis:		
-Patient's age then	53.0 (12.8) ^a , 33.0–81.0	51.2 (12.6) ^a , 33.0–72.0
-Subject's age then	24.2 (11.9) ^a , 1.0–48.0	31.0 (7.6) ^b , 16.0–43.0
-Years since diagnosis	20.8 (9.7) ^a , 5.4–42.8	9.4 (6.1) ^b , 1.0–21.6
Death from Cancer:		
-Parent's age then	62.4 (14.7), 35.0–83.5	n/a
-Subject's age then	31.2 (13.9), 3.0–52.0	n/a
-Years since death	14.0 (11.3), 1.5–42.8	n/a

Groups with same superscript are not significantly different ($p > .1$).

Table 2). As none of these variables were significantly related to the distress or perceived risk measures in the two Risk Subgroups (all p 's $> .2$), they were not included as covariates in the analyses. No significant differences were seen for any other demographic or diagnosis-related variables.

Effects of Family History of Breast Cancer on General Distress, Intrusive Thoughts and Avoidance and Perceived Risk

First, we sought to confirm that having a family history of breast cancer was associated with higher levels of general distress (BSI), intrusive thoughts and avoidance about breast cancer, and perceived risk. Unlike our previous report (5), repeated measures analysis of covariance using the general severity index of the BSI as a dependent variable yielded no significant difference between the groups on this measure of general distress.

Repeated measures ANCOVA using IES scores on the two Assessment Days yielded a significant Group main effect, $F(1,85) = 12.45$, $p < .001$. Post-hoc analyses showed that the Risk Group had significantly higher levels than did the Comparison Group on both Assessment Days (Duncan, $p < .05$). No significant interaction effects by Assessment Day were found, suggesting that differences in IES scores remained elevated in the Risk Group regardless of the presence or absence of the cancer-related cue. In addition, there were no significant interactions by IES subscales, suggesting that intrusive thoughts and avoidance showed the same patterns of differences between the groups.

Finally, the Risk Group also had higher perceived risk scores than did the Comparison Group, as shown by a significant main effect, $F(1,85) = 28.14$, $p < .0001$ (Risk Group: $M = 64.19$, $SD = 23.61$; Comparison Group: $M = 31.99$, $SD = 22.02$).

Effects of Experiencing the Death of a Parent from Cancer on General Distress, Intrusive Thoughts, and Avoidance

To allow examination of the contribution of having experienced the death of a parent from cancer to these women's levels of distress and perceived risk, the Risk Group was split into the two subgroups. Repeated measures ANCOVA comparing GSI scores across the three groups (the Comparison Group and Risk Subgroups 1 and 2) again revealed no significant differences, suggesting that the three groups were similar on this measure of general distress.

Analyses on the IES yielded a significant main effect of Group, $F(2,84) = 9.69$, $p < .001$, when marital status and age were

controlled (see Figure 1). There was no significant main effect of Assessment Day, no Group by Day interaction, and no significant interactions by IES subscales. Post-hoc analyses showed that women at familial risk who had experienced the death of a parent from cancer (Risk Subgroup 1) had the highest intrusive thoughts and avoidance regarding breast cancer across assessment days, whereas those women at familial risk whose parents had not died from cancer (Risk Subgroup 2) were statistically comparable to normal-risk women (Duncan, $p < .05$). This is consistent with the idea that the heightened intrusive thoughts and avoidance in women at familial risk can, at least in part, be explained by their experience of parental death from cancer.

Death of a Parent from Cancer and Perceived Risk

In order to examine the contribution of the death of a parent from cancer on subjects' levels of perceived risk for breast cancer, we conducted an ANCOVA comparing the two Risk Subgroups to the Comparison Group on this variable. Results showed a significant main effect for Group, $F(2,84) = 17.98$, $p < .001$, after marital status and age were covaried. As expected, Risk Subgroup 1, whose parent(s) had died of cancer, reported significantly higher levels of perceived risk than the other two groups, whereas the Comparison Group had the lowest scores on this measure (Risk Subgroup 1: $M = 70.35$, $SD = 23.71$; Risk Subgroup 2: $M = 52.66$, $SD = 19.20$; Comparison Group: $M = 32.00$, $SD = 22.02$). All three groups were significantly different from one another (Duncan, $p < .05$).

FIGURE 1: Impact of Event Scale (IES).

Perceived Risk, Intrusive Thoughts, and Avoidance

Among the women with family histories of breast cancer, those whose parent(s) had died of cancer had higher levels of intrusive thoughts and avoidance as well as higher perceived risk than those whose parent(s) had not died of cancer. It was therefore of interest to examine the possibility that perceived risk might mediate the relations between the experience of a death of a parent from cancer and intrusive thoughts and avoidance.

In accordance with the conceptualization of mediation described by Baron and Kenny (24), we first ascertained the effects of Risk Subgroups on the IES and perceived risk scores omitting the Comparison Group from the analyses. Risk Subgroup 1 was significantly higher on both IES scores: $F(1,44) = 5.40, p < .03$, ($r^2 = .11, B = .33$), and perceived risk, $F(1,44) = 6.58, p < .02$, ($r^2 = .13, B = .36$). We then used regression analyses to test the possible mediating effect. First, we examined whether the hypothesized mediator (perceived risk) predicted the dependent variable (IES scores at the two Assessment Days) using a repeated measures regression equation. Perceived risk was a significant predictor of IES scores on both Assessment Days as shown by a significant main effect, $F(1,44) = 11.54, p < .002$, ($r^2 = .21, B = .46$) and no significant interactions. The results suggest that high perceived risk scores predict high levels of intrusive thoughts and avoidance regarding breast cancer.

Second, if perceived risk acts as a mediator of the differences between the Risk Subgroups on IES scores, then the effect of Risk Subgroup on IES scores should be reduced or eliminated when perceived risk is statistically controlled (24). Perceived risk and Risk Subgroup variables were entered consecutively into a repeated measures multiple regression correlation which yielded a significant main effect for perceived risk on the IES, $F(1,43) = 7.34, p < .01$, and a non-significant effect for Risk Subgroup, $F(1,43) = 1.80, p > .18$ ($r^2 = .03, B = .19$) (see Figure 2). When the IES was broken down into its subscales of Intrusive Thoughts and Avoidance, analyses yielded no Subscale by Risk Subgroup interactions. These results suggest that perceived risk significantly mediated the subgroup difference in the levels of intrusive thoughts and avoidance regarding breast cancer. The absence of a significant interaction by Assessment Day indicates that this mediating effect holds irrespective of the presence or absence of mammography screening.

We also examined the possibility that the women's objective risk for breast cancer may significantly contribute to this mediating effect. We found a significant correlation between perceived risk and objective risk scores calculated according to the Claus Model (22), $r = 0.34, p < .02$. However, there was no significant correlation with objective risk according to the Gail Model (21), nor was there a significant difference among the Risk Subgroups on objective risk for either model (see Table 2). There was also no correlation between either model of objective risk and IES scores. Finally, we examined whether objective risk may account for the relation between perceived risk and IES scores. For this purpose, we included objective risk scores from each model as covariates in a regression equation using perceived risk as a predictor of IES scores and found no change in the significant relation between perceived risk and IES. From this, we can conclude that the mediating effect of perceived risk described above was not confounded by the women's objective risk for breast cancer.

Additional Analyses on Factors Related to Cancer Death of the Parent on IES Scores and Perceived Risk

In addition to the main analyses regarding the relations between the parent's death from cancer on perceived risk and

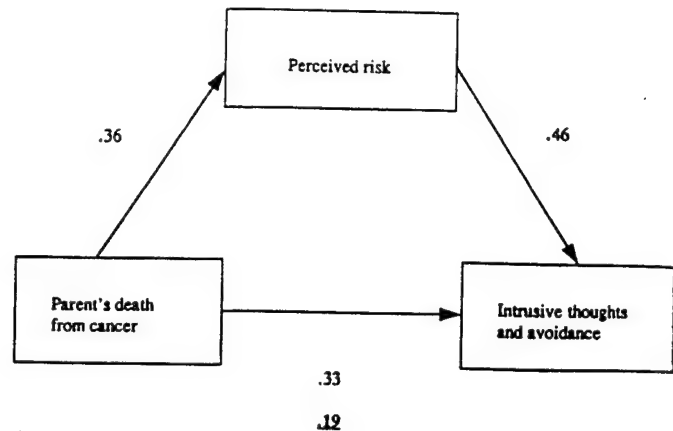

FIGURE 2: Parent's death from cancer, perceived risk, and intrusive thoughts and avoidance.

distress, we conducted some exploratory analyses examining variables related to the parent's death that were available to us in order to further characterize distress related to this potentially traumatic event. These included age of the subjects at the time the parent died, age of the parent then, and recency of the parent's death⁴ (see Table 2). None of these characteristics showed significant associations with IES scores regarding breast cancer or perceived risk for breast cancer in these women.

DISCUSSION

The main goal of the present study was to examine the contribution of having experienced the death of a parent from cancer to current intrusive thoughts, avoidance, and perceived risk regarding breast cancer in women at familial risk for this disease. In order to address this aim, we first sought to replicate previous findings that women with family histories of breast cancer have more distress, in the presence or absence of a cancer-related cue, than women without such family histories (5). These variables were assessed in women at familial risk for cancer on two separate occasions: on a day of routine mammography screening (Assessment Day 1) and on a day with no explicit cancer-related stressor (Assessment Day 2) four to eight weeks after notification of normal mammography results. The Risk Group had significantly higher levels of intrusive thoughts and avoidance regarding breast cancer than did the Comparison Group, which confirmed the previous report by Valdimarsdottir et al. (5). This was true on the day of mammography and one to two months later. However, unlike that previous study which found women with family histories of breast cancer to have higher general distress (GSI) on the BSI, we found no differences between the groups on that measure. Differences in recruitment strategies may account for the higher distress found in the former study, because Valdimarsdottir et al. (5) recruited women from a high-risk clinic, whereas we recruited women through three different mammography screening programs not exclusively targeted to women at high risk for breast cancer. The heightened levels of cancer-specific intrusive thoughts and avoidance, which have been reported in several studies (4,5), may be the predominant symptoms of distress in these women. Intrusive thoughts and avoidance have also been associated with lower levels of adherence to mammography screening (3,4), which underscores the importance of examining the sources of these symptoms more closely.

Further, women in the Risk Group had significantly higher levels of perceived risk for breast cancer than women in the Comparison Group. Previous studies have shown that women with

family histories of cancer estimate their own risk to be high. For example, Valdimarsdottir et al. (5) reported women with family histories of breast cancer to have similar levels of perceived risk as the women in our study (i.e. $M = 59.2$), and these levels were significantly higher in these women than those reported by the Comparison Group. Other studies have reported high levels of perceived risk using slightly different measures (3,4); however, none of these studies included a comparison group. It is of interest in the present study that perceived risk was significantly positively correlated with objective risk calculated according to the Claus model but not to the Gail model. The two models use different variables to calculate the risk estimates, which often vary based upon which model was used. The Claus model relies more heavily on family history of cancer, whereas the Gail model includes the person's past medical history (see Measures). It is conceivable that women are more aware of their risk contribution based on family history than on personal medical variables. This may partly be due to media attention devoted to the genetic risk factors of breast cancer. This could be the reason why only the Claus figures were correlated with perceived risk in these women. Only one other study has reported a correlation between perceived risk and objective risk factors (8), however, in that case the correlation was negative. Several differences between that study and the present one may account for this difference in finding, including the use of different objective and subjective risk measures. It should be noted that the lack of uniformity of subjective and objective risk assessments makes comparisons across studies often difficult, and the standardization of this important measure needs to be addressed in future research.

Having established the higher levels of distress and perceived risk in this sample of women, our main goal was to examine whether having experienced the death of a parent from cancer may contribute to the individual variability in some of these symptoms. The present data suggest this to be the case for intrusive thoughts and avoidance regarding breast cancer. While the two Risk Subgroups did not differ on general distress (BSI), the women whose parent(s) had died of cancer had significantly higher scores on the IES than women in the Risk Subgroup who had not experienced this life event or women in the Comparison Group. There was no significant difference in IES scores between the Risk Subgroup who did not experience a parent's death of cancer and the Comparison Group. While several studies have found that women with family histories of breast cancer have elevated levels of intrusive thoughts and avoidance regarding cancer, the issue of why these symptoms occur has rarely been addressed. Our data suggest that past cancer-related events may be strong determinants of later distress and that having experienced a parent's death from cancer may be a potent stressor that may make the threat of breast cancer especially salient for these women. It is tempting to speculate that the experience of the parent's death from cancer, in addition to their diagnosis which all the women in our risk group had experienced, may change the meaning of cancer from a potentially curable illness to a death threat. This may heighten these women's distress about cancer in general. However, the death of the parent from cancer does not account for all of the variance in intrusive thoughts and avoidance about breast cancer, suggesting that other predictors also need to be explored.

The fact that the women's perceived risk for breast cancer was affected by the experience of a parental death from cancer may be interpreted in accordance with theories proposed by Janoff-Bulman (17). This author has suggested that traumatic or stressful life events (such as the death of a parent) may challenge one's personal assumptions of invulnerability to harm and injury. While

the majority of people tend to have a rather unrealistic sense of invulnerability, that is, they believe the likelihood of "bad things" happening to them to be very low (25), a traumatic event (e.g. the death of a parent from cancer) may challenge these assumptions. It has been suggested that the change in assumptions about one's personal vulnerability may be specific to the type of event of which the individual was a victim [e.g. children whose parents divorced have more negative assumptions specifically about marriage, not about the world in general (26)]. In the present study we found that women whose parent(s) had died of cancer felt more vulnerable to developing breast cancer. The specificity of increased perceived vulnerability will be an interesting question to explore in future studies.

The third aim of the study was to examine the role of perceived risk as a potential mediator for the association between a parent's death from cancer and intrusive thoughts and avoidance concerning breast cancer in women with family histories of breast cancer. Results were consistent with this possibility. Women who had experienced the death of a parent from cancer had the highest levels of perceived risk which, in turn, accounted for much of their heightened levels of intrusive thoughts and avoidance. Although we found no selective effects of intrusive thoughts versus avoidance, our results are consistent with the theories put forth by Janoff-Bulman and Horowitz (17,27,28). The discrepancies between one's previous assumptions of invulnerability and the new feeling of vulnerability conveyed by the death of a parent or other events are thought to create a conflict that may gradually be resolved by intrusive thoughts and avoidance. In theory, these coping processes may be used until reintegration of the new information and the person's existing mental models and world assumptions is achieved and cognitive harmony is restored (27). Our data are in support of this model. Intrusive thoughts and avoidance scores were highly correlated in this study, and it appears from the lack of significant interactions by IES subscales that these coping processes may be affected similarly by the predictors.

It should be noted with regard to these findings that given that the aim of the study was to assess cancer-related distress, we chose to measure intrusive thoughts and avoidance about breast cancer. Had we focused the IES on the death of the parent specifically, it is likely that the mediating role of perceived risk between the effect of parental death and IES scores would not have been as strong. It is also interesting that in this study, recency of parental loss (ranging from 1 to 43 years) to cancer was not associated with higher levels of intrusive thoughts and avoidance or perceived risk. Again, had we focused the IES on the death of the parent from cancer, we may well have obtained the expected relation. Finally, we did not find any associations between other diagnosis-related variables, such as number of affected first-degree relatives, time since their cancer diagnosis, and subjects' distress levels. The relations between specific characteristics of a woman's past experience with family history of cancer and her levels of distress should be addressed more systematically in future studies.

Another hypothesis dealt with the effects of a cancer-specific cue in this study. Previous research has suggested that individuals who have experienced stressful events such as bereavement or separation may be more sensitive to cues associated with that event (34). Based on those findings, we expected that women at familial risk who had experienced the death of a parent from cancer would show a greater increase in intrusive thoughts and avoidance at the time of mammography screening than women who did not have the experience of parental death from cancer. However, the absence of a statistically significant interaction did not support this

idea. That is, women in Risk Subgroup 1 had significantly higher scores on the IES independent of this cancer-specific stressor (mammography). It is possible that mammography may not present a cue specific to memories or distressing thoughts related to the parent's death from cancer. Mammography, which is a diagnostic procedure, may be a more specific cue for triggering memories of the parent's diagnosis of breast cancer, an event which all the women in the Risk Group had experienced. Explanations of this effect can, however, merely be speculative at this point.

Several limitations of this study provide suggestions for future research in this area. The sample size in our study did not allow us to conduct more fine-grained analyses of parental death as a life-event. For example, we were not able to compare women whose parent(s) died of cancer with those whose parent(s) died of other causes because there were too few subjects in the latter category. In addition, our relatively small sample size did not allow us to conduct analyses by gender of the deceased parent. Horowitz et al. (13) found that maternal death was associated with more depression and intrusive symptoms than paternal death. Future studies with larger sample sizes may be able to confirm these findings, which may be especially important in women at risk for breast cancer. Further, we were not able to assess the differential impact of having had one versus two parents die of cancer or that of having a second parent who died of causes other than cancer. These are interesting questions that should be explored in future studies in this population. In addition, further research should be conducted to study the contribution of other dispositional factors that may increase or reduce women's vulnerability to developing stress symptoms.

It could be argued that the women in our Risk Group may not be representative of the general population of women at familial risk because they were participating in mammography screening programs. However, based on the literature suggesting that women who are less distressed are more likely to comply with mammography screening guidelines (3,4), we may expect our data to underestimate the levels of distress that may be found in this population. Future studies should address this issue by including women at familial risk who do not attend such screening programs.

As our Comparison Group, we chose women without family histories of breast cancer who were not undergoing mammography screening at the time of data collection. This enabled us to control for the day-to-day distress in women with similar demographic characteristics living in the same urban community. This is an important control that has only rarely been used in the study of women at familial risk for cancer. It did not, however, allow us to separate the effects of distress due to mammography versus that of having a family history of breast cancer on Assessment Day 1. The finding that intrusive thoughts and avoidance about breast cancer remained elevated in the Risk Group on Assessment Day 2 (a non-mammography day) suggests that distress in these women may be primarily due to their family history. This should be addressed in future studies including a comparison group of normal-risk women from the community who are currently undergoing mammography screening.

The present study on women with family histories of breast cancer is one of the few to incorporate any type of comparison group or to use a longitudinal design. The study not only confirmed previously reported findings that women with family histories of breast cancer have higher levels of intrusive thoughts and avoidance about cancer, but also identified an objective discrete event (the death of a parent from cancer) as a possible contributing

source of these symptoms. In fact, our data suggest that only those women at familial risk whose parent(s) had died of cancer reported significantly higher levels of intrusive thoughts and avoidance than the Comparison Group, suggesting that parental death may be an important issue to address in future studies of this population. These findings also put into question the potential importance of other current or past cancer-related events that these women may experience, such as caregiving for a parent with cancer, illness of friends and more remote relatives, etc. In addition, having a parent who is currently under active treatment for cancer may be a significant stressor for these women that should be taken into account. With few exceptions (5), most of the studies of women at familial risk for cancer do not explicitly exclude those cases. In fact, women with family histories of cancer are oftentimes recruited through their family members who are currently undergoing treatment for cancer (4,8). Future studies should include current treatment of the family member as a potential additional life stressor that may contribute to these women's distress.

The findings from the present study may have implications for intervention strategies. Recent studies (35,36) have shown that breast cancer risk counselling is effective in helping women with family histories of breast cancer gain a better understanding of their personal risk for breast cancer and in reducing their cancer-specific distress (IES). Another study examining the effects of problem-solving training reported that those women who practiced problem-solving strategies regularly had reduced cancer-specific distress on the IES (37). Our data suggest that there may be subgroups of women who may be especially prone to distress regarding breast cancer; and that it will be useful to identify those women whose parents have died of cancer, as they may be in particular need of counselling. In addition, exploring past cancer-related events as possible sources of these women's distress may prove beneficial in helping women reduce their distress. Specifically, counsellors could address women's reactions to a parent's death from cancer and examine its impact on distress and their exaggerated perceived risk for developing breast cancer. Our data also indicate that the women's high perceived risk may be an important mediator between their experience of a parent's death from cancer and distress. If women's risk perceptions can be rectified to more closely approximate their actual objective risk, it may help to reduce their distress. Finally, cognitive-behavioral strategies may be useful in helping women reduce their distress about breast cancer, to cope with cancer-related events such as deaths in family members, and to identify and utilize effective coping and screening behaviors.

Decision-Making About Genetic Testing Among Women at Familial Risk for Breast Cancer

PAUL B. JACOBSEN, PhD, HEIDDIS B. VALDIMARSDOTTIR, PhD, KAREN L. BROWN, MS, AND
KENNETH OFFIT, MD

Objective: Recent identification of the breast-ovarian cancer susceptibility gene *BRCA1* and the breast cancer susceptibility gene *BRCA2* have raised the possibility of clinical genetic testing for breast cancer susceptibility. This study examined decision-making about future susceptibility testing among women at familial risk for breast cancer. Based on the transtheoretical model, it was hypothesized that readiness to undergo testing would be related to the ratio between the perceived advantages (pros) and disadvantages (cons) of learning one's susceptibility status. **Methods:** Seventy-four women with one or more first-degree relatives with breast cancer were recruited before a routine mammogram. Participants completed measures assessing readiness to undergo testing, perceived pros and cons of testing, and perceived breast cancer risk. Family history data was used to calculate empiric genetic risk of developing breast cancer. **Results:** Forty-six per cent of participants planned to seek genetic testing as soon as possible, 35% planned to seek testing in the future, and 19% did not plan to seek testing. As expected, greater readiness to undergo testing was associated with a positive decisional balance (pros > cons). Older age and greater perceived risk (but not empiric risk) also were associated with greater readiness. **Conclusion:** The readiness of many women to seek breast cancer susceptibility testing can be attributed, in large part, to their perceptions that the advantages outweigh the disadvantages. Examination of these perceptions suggests that notification of carrier status may have significant effects on women's psychological well-being and breast cancer surveillance and prevention behaviors.

Key words: genetic testing, breast cancer, decision-making, transtheoretical model.

INTRODUCTION

Epidemiologic data suggest that 5% to 10% of all cases of breast cancer are attributable to one or more susceptibility genes that are inherited in an autosomal dominant fashion (1, 2). The locations of two such genes have been identified recently. A major breast-ovarian cancer susceptibility gene, known as *BRCA1*, was mapped by linkage to chromosome 17 in 1990 (3) and was isolated by a positional cloning strategy in 1994 (4). A second gene predisposing to breast cancer, labeled *BRCA2*, was identified on chromosome 13 by linkage analysis (5) and also has been isolated recently (6). Available data suggest that women who inherit *BRCA1* mutations have an 80% to 90% lifetime risk of developing breast cancer and

an increased risk of developing ovarian cancer (7). Inheritance of *BRCA2* mutations also confers a high risk of developing breast cancer, but not necessarily an increased risk of developing ovarian cancer (6).

With the recent isolation of the *BRCA1* and *BRCA2* genes, it is becoming possible to test individual family members affected by breast or ovarian cancer to determine their carrier status. Once a mutation has been established in an affected family member, unaffected family members then can be tested to determine their carrier status. Once the full spectrum of *BRCA1* and *BRCA2* mutations is identified, it may be possible to determine genetic susceptibility to breast cancer solely by testing unaffected individuals (8).

These developments are expected to lead to a considerable demand for genetic susceptibility testing among women with family histories of breast cancer (7). Three studies have examined this issue by assessing interest in genetic testing among women at familial risk for either breast or ovarian cancer. Lerman et al. (9) examined interest in *BRCA1* testing among 112 women who had at least one first-degree relative diagnosed with ovarian cancer. Seventy-five per cent of this sample reported they would "definitely" want testing and 25% said they would "probably" want testing. Struwing et al. (10) assessed interest in *BRCA1* testing among 91 women

who were members of "hereditary breast-ovarian cancer families" participating in genetic linkage research at the National Cancer Institute. Seventy-nine per cent of this sample reported they would "definitely" want testing and 16% said they would "probably" want testing. Most recently, Lerman et al. (11) assessed interest in genetic testing for breast cancer susceptibility among 105 women who were first-degree relatives of breast cancer patients. Ninety-one per cent of this sample indicated that they would want testing.

These same studies also examined women's reasons for wanting or not wanting to be informed of their genetic susceptibility status. The most commonly cited reasons for wanting testing were: to learn whether one's children are at risk (9-11), to increase use of screening methods (9-11), to take better care of oneself (10, 11), and to be reassured (12). The most commonly cited reasons for not wanting testing were: worries about insurability (10, 11), concerns about test accuracy (11), and worries about emotional reactions (11).

The purpose of the present study was to examine the relation between women's interest in testing and their reasons for wanting or not wanting to be informed of their genetic susceptibility status. To do so, the study used two constructs included in the transtheoretical model of behavior change (13, 14). This model has been presented as an integrative and comprehensive theory of behavior change with potentially wide applicability (15).

The first construct borrowed from the model is behavioral stage of adoption. Previous research (15, 16) has identified a sequence of stages through which people are likely to proceed before adopting new health behaviors such as quitting smoking or going for routine mammograms. These stages include: precontemplation (presently not performing the behavior and not intending to start in a given time period), contemplation (presently not performing the behavior but considering starting in a given time period), and preparation (taking the first steps to change behavior). In the present study, assessment of behavioral stage of adoption required modification inasmuch as genetic testing is neither an ongoing behavior (eg, smoking cessation) nor a recurring behavior (eg, mammography screening). Moreover, genetic testing for breast cancer susceptibility is not currently available on a widespread basis. To address these issues, stage of adoption was operationalized by asking participants to imagine that an individually administered genetic test for breast cancer susceptibility was currently available and to indicate their readiness to take such a test. Participants

could indicate that they planned to take the test as soon as possible (preparation), planned to take the test in the near future (short-range contemplation), planned to take the test but not in the near future (long-range contemplation), or did not plan to take the test (precontemplation).

The second construct borrowed from the transtheoretical model is decisional balance. In previous research, this construct has been measured by assessing the relative strength of the perceived advantages (pros) and disadvantages (cons) of adopting a target behavior (17). Based on previous research using the transtheoretical model (15), it was hypothesized that women who did not plan to undergo genetic testing would have a negative decisional balance (cons > pros) and that women who planned to undergo genetic testing as soon as possible would have a positive decisional balance (pros > cons). Women who planned to be tested sometime in the future were expected to have a decisional balance close to the neutral or zero point of pros equaling cons.

In addition to testing hypotheses based on the transtheoretical model, the present study explored the relation of perceived breast cancer risk as well as medical and demographic factors to readiness to undergo genetic testing. With regard to demographic factors, we examined whether age, marital status, or level of education were related to readiness. With regard to medical factors, we examined whether a statistical estimate of genetic risk (16) or previous history of breast biopsy were related to readiness. These factors were selected for study based on a review of the literature on genetic testing for heritable cancers (9-12, 18).

METHODS

Subjects

Participants were recruited from three mammography screening programs in New York City. To be eligible for the current study, women attending these programs had to: a) be 18 years of age or older; b) be able to read and write English; c) have no prior history of breast or ovarian cancer; d) have one or more first-degree relatives (mother, sister, or daughter) diagnosed with breast cancer; e) be scheduled for a routine mammogram within the next week; and f) provide written informed consent for study participation. Ninety-four women meeting these criteria were invited to participate in the current study and 82 agreed. Among women who declined to participate ($N = 12$), most cited "lack of time" as the principal reason. Eight women provided incomplete data; thus, results are reported for 74 women (Site A = 48, Site B = 12, and Site C = 14). Women who provided complete data did not differ from women who provided incomplete data in terms of

BREAST CANCER GENETIC TESTING

age, marital status (married/not married), education (high school or less/college), or prior history of breast biopsy (yes/no) ($p \geq .25$).

Procedure

Potential participants were identified using each clinic's computerized appointment tracking system. Approximately 1 week before her scheduled mammogram, each potential participant was contacted by telephone and given a description of the study procedures. Women interested in participating subsequently met with a research assistant in the clinic waiting area when they arrived for their scheduled mammogram. At this time, the study was described again and written informed consent was sought. Women who provided informed consent then completed a set of questionnaires in the clinic waiting area. Questionnaires relevant to the present study are described below.

Measures

Demographic Questionnaire. Age, education, race/ethnicity, and marital status were assessed using a standard self-report form (19).

Medical Chart Review. Medical charts were reviewed before recruitment to determine whether participants met the eligibility criteria of having a first-degree relative with breast cancer and not having a personal history of breast or ovarian cancer. After recruitment, medical charts were reviewed again to determine whether participants had a prior history of breast biopsy and to calculate participants' empiric genetic risk for breast cancer. At the time of their enrollment in each screening program, women provided information about the occurrence of breast cancer and the age of onset of breast cancer in both their first-degree and second-degree relatives. This information was updated at the time written informed consent was obtained and was converted into an empiric genetic risk score using tables derived from a population-based case-control study of breast cancer development (16). The resulting scores represent the probability (expressed in percentages) that each participant will develop breast cancer by age 79 years.

Perceived Risk of Breast Cancer Scale. Perceived risk was assessed by having participants rate from 0 (not at all likely) to 100 (extremely likely) the likelihood that they would ever develop breast cancer (19).

Readiness Scale. Participants read the following description adapted from a previous study (9) before rating their readiness to undergo genetic testing for breast cancer:

"In a small number of families, several family members develop breast cancer, often at younger ages. Scientists believe that, in some of these families, women who develop breast cancer have inherited a particular gene that makes them susceptible to cancer. This gene is passed down from generation to generation in these families. Some family members will inherit the gene and others will not. In the near future, it may become possible to perform a blood test to determine which members of these families have this breast cancer gene. A woman who has the gene would have an extremely high risk of developing breast cancer in her lifetime. A woman who didn't have the gene would have the same risk of developing breast cancer as a woman with no family history of breast cancer."

After reading this statement, participants were instructed to imagine that the test was currently available and to indicate what

their plans would be. Response options were: a) I plan to take the test as soon as possible (within the next 30 days); b) I plan to take the test sometime in the near future (within the next 6 months); c) I plan to take the test, but not in the near future (not within the next 6 months); d) I do not plan to take the test within the next 6 months, but I may change my mind; or e) I do not plan to take the test within the next 6 months and I am not likely to change my mind.

Decisional Balance Scale for Breast Cancer Genetic Testing. A self-report scale was administered in conjunction with the Readiness Scale to assess perceptions of the potential advantages (pros) and disadvantages (cons) of undergoing genetic testing for breast cancer. The scale consisted of 21 items (10 pros, 11 cons) described as, "a list of issues a woman might consider in deciding whether or not to take the genetic test described above." Items were drawn from interviews with women at familial risk for breast cancer, discussions with genetic counselors working at a major cancer center, and reviews of publications describing psychosocial issues in genetic counseling and testing for heritable breast cancer (7, 12). Participants rated the degree to which they agreed or disagreed with each item on a 5-point scale (1 = strongly disagree, 3 = neither agree or disagree, 5 = strongly agree). Ratings of potential advantages were summed to yield a total pros score and ratings of potential disadvantages were summed to yield a total cons score. Reliability analysis indicated that the pros and cons scales were internally consistent (α coefficients = .80 and .64, respectively). Correlational analysis suggested that the two scales were statistically independent of each other ($r = -.15$, $p = .21$). As in previous research (17, 20) raw scores for the pros and cons scales were converted into standard *T* scores (mean = 50, *SD* = 10) to provide a common metric. A summary decisional balance measure was then created by subtracting the cons *T* scores from the pros *T* scores (20).

RESULTS

Sample Characteristics

The participants had a mean age of 44 years (*SD* = 6.09, range = 32 to 59). Ethnic/racial characteristics were: Caucasian, 69; African-American, 2; Hispanic, 1; Asian, 1; and other, 1. Fifty-six of the participants were married, 6 were divorced or separated, 1 was widowed, and 11 were never married. Fifty-nine participants had a college degree, 13 had attended college but not graduated, and 2 had not attended college. Twenty-nine participants (39%) had previously undergone a breast biopsy and, in all cases, the results had yielded no evidence of malignancy. The average participant was estimated to have an 18% probability of developing breast cancer by age 79 (*SD* = 8.91, range = 11 to 41) because of her family history of breast cancer.

Readiness to Undergo Testing

If an individually administered test for genetic susceptibility to breast cancer were currently avail-

able, 46% of participants ($N = 34$) would seek testing as soon as possible (within the next 30 days), 30% ($N = 22$) would seek testing in the near future (within the next 6 months), and 5% ($N = 4$) would seek testing in the more distant future. Sixteen per cent ($N = 12$) would not seek testing but thought they might change their minds, and the remaining 3% ($N = 2$) would not seek testing and thought they were unlikely to change their minds. In subsequent analyses, participants were divided into three groups: those who planned to seek testing as soon as possible ($N = 34$); those who planned to seek testing in the future ($N = 26$); and those who did not plan to seek testing ($N = 14$).

Perceived Pros and Cons of Testing

The most commonly perceived pros and cons were identified by tabulating the percentage of women who agreed (4) or strongly agreed (5) with each decisional balance item. Five pros were endorsed by more than 50% of participants (Table 1). The majority of women thought that knowing they *carried the gene* would: help their female relative decide whether to undergo testing, motivate them to perform breast self-examination more frequently, help them decide whether to go for more frequent mam-

mograms, and help them decide whether to undergo preventive surgery. The majority of women also thought that knowing they *did not carry the gene* would reduce their concerns about developing breast cancer.

Two cons were endorsed by more than 50% of participants (Table 2). The majority of women thought that knowing they *carried the gene* would increase their concerns about developing breast cancer and would cause them to worry more about female relatives who might also be carriers.

Factors Associated with Readiness to Undergo Testing

Statistical analyses were conducted to examine the relation of demographic, medical, and psychosocial factors to readiness to undergo genetic testing for breast cancer (Table 3). χ^2 analyses were performed for categorical measures (eg, marital status) and one-way analyses of variance were performed for continuous measures (eg, age). As a follow-up to significant one-way analyses of variance, pairwise mean comparisons were conducted (using the least

TABLE 1. Perceived Pros of Genetic Testing

Pros	Agree or Strongly Agree
My concerns about developing breast cancer would be reduced if I knew I did not carry the gene.	82%
If I were found to carry the gene, it would help my daughter(s) or sister(s) decide whether to undergo genetic testing.	81%
Knowing that I carry the gene would motivate me to perform breast self-examination more frequently.	77%
Knowing that I carry the gene would help me decide whether to go for more frequent mammograms.	66%
Knowing that I carry the gene would help me decide whether to undergo preventive surgery.	64%
My sense of uncertainty about the future would be reduced if I knew whether or not I carried the gene.	49%
Knowing whether or not I carry the gene would increase my sense of personal control.	45%
Knowing whether or not I carry the gene would help me make important life decisions (eg, getting married, having children).	42%
Knowing that I do not carry the gene would greatly improve my quality of life.	41%
Knowing that I do not carry the gene would improve how I feel about myself.	30%

TABLE 2. Perceived Cons of Genetic Testing

Cons	Agree or Strongly Agree
My concerns about developing breast cancer would increase if I knew that I carried the gene.	85%
Knowing that I carry the gene would cause me to worry more about other family members who could be carriers (eg, mother, sisters, daughters).	72%
Knowing that I do not carry the gene would not be helpful since I could still develop breast cancer.	39%
Knowing that I do not carry the gene would not reduce my concerns about developing breast cancer.	38%
If I were found to carry the gene, it would jeopardize my insurance coverage or lead to problems with my employers.	34%
Knowing that I carry the gene would leave me in a state of hopelessness and despair.	27%
Knowing that I carry the gene would worsen my quality of life.	20%
I feel I already know my chances of getting breast cancer, so I wouldn't learn anything more from being tested.	15%
If I were found to carry the gene, it would lead to marital or family problems.	7%
Testing is not worthwhile because it could yield inconclusive results about whether I carry the gene for breast cancer.	5%
If I were found to carry the gene, it would cause others to view me negatively.	5%

^f $F(2,46) = 28.06, p < .0001$.

significance difference test) to identify specific subgroup differences.

With regard to demographic factors, results showed that readiness was related to age but not to education or marital status. Follow-up analyses indicated that the women who planned to be tested as soon as possible were older than the women who planned to be tested in the future and the women who did not plan to be tested. With regard to medical factors, results indicated that readiness was not related to either previous history of breast biopsy or empiric genetic risk.

With regard to psychosocial factors, results showed that readiness was related to perceived risk. The women who planned to be tested as soon as possible perceived themselves to be at greater risk for breast cancer than the women who planned to be tested in the future and the women who did not plan to be tested. Results also showed that readiness was related to the perceived pros and cons of genetic testing and to the summary decisional balance measure. Subgroup analysis of pros scores indicated that the women who planned to be tested as soon as possible perceived more advantages than the women who planned to be tested in the future and the women who did not plan to be tested. Subgroup analysis of cons scores indicated that the women who did not plan to be tested perceived more disadvantages than the women who planned to be tested in the future and the women who planned to be tested as soon as possible. Subgroup analysis of the

decisional balance measure scores indicated that the women who planned to be tested as soon as possible had a more positive decisional balance (pros > cons) than the women who planned to be tested in the future and the women who did not plan to be tested. Furthermore, women who planned to be tested in the future had a more positive decisional balance (pros > cons) than women who did not plan to be tested.

To determine the relative strength of pros and cons within each readiness subgroup, mean pros and cons scores were directly compared using paired t tests. Among women who planned to be tested as soon as possible, mean pros scores were significantly greater than mean cons scores, $t(33) = 4.57, p < .0001$. Among women who planned to be tested in the future, mean pros and cons were not significantly different, $t(25) = -.53, p = .60$. Finally, among women who did not plan to be tested, mean cons scores were significantly greater than mean pros scores, $t(13) = -5.40, p < .0001$.

In light of results indicating that readiness to undergo genetic testing was related to age and perceived risk as well as decisional balance, a multivariate approach was used to determine the unique contribution of decisional balance to prediction of readiness scores. Specifically, a hierarchical multiple logistic regression analysis of readiness scores was conducted in which decisional balance was entered into the model after accounting for the predictive value of age and perceived risk (Table 4).

TABLE 4. Logistic Regression Analysis of Readiness to Undergo Genetic Testing

Variable Entered	Parameter Estimate	SE	Wald χ^2	p
Age	-0.09	0.05	4.01	.05
Perceived risk	-0.03	0.01	5.47	.02
Decisional balance	-0.11	0.02	21.61	<.0001

χ^2 for covariates (3 df) = 47.66, $p < .0001$.

After controlling for the predictive value of the other two variables, consideration of the summary decisional balance score significantly improved the ability of the model to predict readiness to undergo genetic testing.

DISCUSSION

In this discussion, we begin by summarizing what was learned about potential demand for genetic testing for breast cancer susceptibility. Next, we consider the utility of decisional balance and other variables for predicting readiness to undergo genetic testing among women at familial risk. Finally, we explore the implications of the study for clinical programs that plan to offer genetic counseling and testing to women at familial risk for breast cancer.

Future demand was estimated in the present study by asking women to imagine that an individually administered genetic test to determine breast cancer susceptibility was currently available and to indicate whether and when they planned to be tested. Eighty-one per cent of the women stated they would plan to be tested. This figure is consistent with results of previous research that 91% to 100% of women with an affected first-degree relative were interested in genetic testing for breast or breast-ovarian cancer susceptibility (9, 10). Among the 81% of participants who stated they planned to be tested, 35% indicated that they would not seek testing as soon as possible. Previous research using the transtheoretical model suggests that this subgroup includes individuals who are likely to be tested within a year as well as individuals who are likely to still be contemplating testing a year later (21). The future behavior of the 19% of women who stated they did not plan to be tested is also uncertain because most of these women indicated they might reconsider their decisions. Taken together, these figures suggest that approximately 50% of women with a first-degree relative affected by breast cancer will immediately seek testing when it becomes widely available. Whether or not demand for genetic testing will greatly exceed

50% among women at this level of familial risk remains unclear.

Findings regarding the relation of empiric risk and perceived risk to readiness to undergo genetic testing were consistent with earlier research. In previous work, no relation was observed between genetic risk (measured in terms of genetic similarity to the affected relative) and interest in testing (10). Similarly, the present study found that empiric genetic risk based on family history of breast cancer (16) was unrelated to readiness to undergo genetic testing. Previous research also indicated that women who perceive themselves to be at higher risk for breast cancer express greater interest in *BRCA1* testing (9, 10). Likewise, in the present study, women who planned to be tested as soon as possible perceived themselves to be at greater risk than women who planned to be tested in the future or women who did not plan to be tested.

Of principal interest in the present study was the possible relation between the perceived pros and cons of testing and readiness to undergo genetic testing. Results confirmed the hypothesis, based on the transtheoretical model, that decisional balance (ie, the relative strength of pros and cons) would predict readiness. These findings are consistent with previous research (15) on the relation of decisional balance to adoption of other health behaviors such as smoking cessation, sunscreen use, and mammography screening. In general, these studies indicate that a negative decisional balance (cons > pros) characterizes individuals who are in the precontemplation stage and a positive decisional balance (pros > cons) characterizes individuals in the preparation or action stages of adopting a health behavior.

In addition to predicting readiness to undergo testing, assessment of pros and cons yielded considerable information about the perceived advantages and disadvantages of genetic testing for breast cancer susceptibility among women at familial risk. With regard to the perceived advantages, the majority of women agreed that learning their genetic carrier status would motivate them to practice breast-self-examination more frequently, help them decide whether to go for more frequent mammograms or undergo preventive surgery, reduce their concerns about developing breast cancer, and help their first-degree relatives decide whether to undergo genetic testing. These findings suggest that providing genetic testing for breast cancer susceptibility to women at familial risk may have several benefits. First, it may encourage these women to increase their surveillance behavior. Second, it may aid these women in their decision-making about either pro-

phylactic mastectomy or oophorectomy. Third, it may assist the first-degree relatives of these women with their decision-making about genetic testing. And fourth, for individuals found not to be carriers of mutated genes, testing may relieve the heightened psychological distress that seems to be common among women at familial risk for breast cancer (19, 22, 23).

As stated previously, women in the present study perceived relatively few disadvantages associated with genetic testing for breast cancer susceptibility. The only disadvantages perceived by a majority of women were that learning their genetic carrier status would increase their concerns about developing breast cancer and cause them to worry more about other family members who could be carriers. These findings are consistent with the views of experts who have warned about the possible negative psychological consequences of informing women of their genetic carrier status (7, 12). In addition, they provide empirical support for the view that women undergoing genetic testing should receive psychological counseling to prevent or ameliorate these reactions (18).

Several limitations of the present study should be noted. First, the outcome in this study was women's readiness to undergo a hypothetical genetic test for breast cancer susceptibility. Whether future genetic tests will possess the same characteristics as this hypothetical test is unknown. Similarly, the relation of the readiness to undergo testing to actual decisions about genetic testing is unknown. Second, the sample in the present study was predominantly white and well-educated. The results reported here may not be generalizable to women at familial risk who possess different demographic characteristics. Third, the present study was limited to women with at least one first-degree relative diagnosed with breast cancer. Possible interest in genetic testing among those who are not at familial risk or are at lesser familial risk was not assessed.

In conclusion, the results of this study indicate that the decision of many women at familial risk to seek genetic testing is related to their perceptions that the advantages of learning their carrier status outweigh the disadvantages. These results are consistent with the transtheoretical model of behavior change and demonstrate its usefulness in understanding decision-making about genetic testing. Responses to the decisional balance measure further suggest that notification of genetic carrier status is likely to have a significant impact on women's psychological well-being and on their breast cancer surveillance and prevention behaviors. These find-

ings underscore the importance of providing counseling to women who undergo genetic counseling for breast cancer susceptibility in order to prevent adverse psychological reactions and to assist in the evaluation of treatment options.

We thank Peter McGuire and Alice Hager for their help in completing the study and preparing the manuscript. This research was supported in part by the T. J. Martell Foundation, American Cancer Society Grant No. PBR-97, and Department of the Army Career Development Award No. J-4139. The views, opinions, and findings contained in this report are those of the authors and should not be considered as an official Department of the Army position, policy, or decision unless so designated by other documentation.

ANNOUNCEMENT

Postdoctoral Research Fellowships

Applications are currently being considered for positions in Clinical Psychopharmacology and Psychobiology at the University of California, San Diego, Department of Psychiatry, on an ongoing basis. This 2 to 3-year NIMH-funded Fellowship in Research Training is intended for psychiatrists and/or psychologists who have recently completed their residency or doctoral training, fellows work under the mentorship of nationally renowned UCSD Department of Psychiatry faculty. Candidates should have a serious interest in an academic or research career.

Clinical research strategies include psychopharmacology, neuroendocrinology, neuroimaging, neuroimmunology, EEG sleep studies and chronobiology, psychophysiology, substance abuse and alcoholism, and molecular genetics.

UCSD is an equal opportunity employer. To receive an application, contact Michael Irwin, MD, Director, Psychopharmacology Research Fellowship, Department of Psychiatry (16A), University of California, San Diego, VA Medical Center, 3350 La Jolla Village Drive, San Diego, CA 92161. Phone (619)552-8585, ext. 2742, email: mirwin@ucsd.edu, website: <http://www.research.ucsd.edu/irwin/fellowship/>

Psychological distress and breast self-examination among Black women with different family histories of breast cancer

Abstract

Studies demonstrating that women with family histories of breast cancer overestimate their personal risk and have high levels of psychological distress that affect their breast cancer screening behaviors have used primarily White samples. We compared Black women with at least one first-degree relative of breast cancer (Risk Group N=23) to Black women without a first-degree relative with breast cancer (Comparison Group, N=32) on measures of psychological distress and breast self-examination (BSE). The Risk Group were more likely to have a high perception of perception of personal risk of developing breast cancer (chi-square = 4.96, $p < .026$) and higher intrusive thoughts about breast cancer ($p < .024$) than women in the Comparison Group. Across Groups, we found that women with a high perception of risk and more intrusive thoughts were less likely to perform BSE at the recommended monthly interval; they either under- or over-performed BSE (chi-square 11.556 $p < .003$). This study confirms previous research demonstrating higher levels of psychological distress among women at familial risk for breast cancer and extends the research to demonstrate its potential impact on BSE among a minority group who have an elevated risk of dying from breast cancer.

Introduction.

Breast cancer is the second leading cause of cancer death in American women. Estimates suggest that more than 180,000 new cases of breast cancer were diagnosed in 1997 and more than 43,000 women died of the disease (1). In the Black community, breast cancer has had a substantial impact. A consistent finding has been that, although Black women are diagnosed with breast cancer slightly less often than White women, the five-year survival rate is significantly lower for Black women (80% for White women versus only 64% for Black women) (2). For both Black and White women having a family history of breast cancer is a risk factor for developing the disease (3). Consequently, Black women with family histories of breast cancer may face the combined threat of being at an increased risk of dying of breast cancer than women in the general population and of being more likely to die from the disease than their White counterparts.

The psychological consequences of having a family history of breast cancer, and its impact on breast cancer screening has not been well-explored in Black women. It is particularly important to understand how having a family history of breast cancer may affect psychological distress and surveillance behavior in these women as they are at highest risk for developing the disease themselves. In this paper we examine how having a family history of breast cancer relates to psychological distress and breast self-examination among Black women.

Association between psychological/cognitive factors and family history

Similar to White women, the strongest predictor of a Black woman's lifetime risk of developing breast cancer is having a family history of the disease (4). The greatest risk is to

women with multiple affected close relatives, suggesting the presence of a mutation in one of the primary breast cancer susceptibility genes (e.g., BRCA1, BRCA2), but even having a single first degree relative with breast cancer can increase risk (5). Accumulating evidence suggests that women with family histories of breast cancer overestimate their risk and may have high levels of distress (e.g., 6-9). Kash et al. (1992) found that 27% of women with family histories of breast cancer experience clinically significant psychological distress. High levels of distress among women with first degree relatives with breast cancer were also reported by Lerman and colleagues (1993), who found that 53% of these women experienced intrusive thoughts about breast cancer (10). Two recent studies that have included concurrent assessments of a comparison group drawn from the community have confirmed that perceived cancer risk and distress levels are higher among women with family histories of breast cancer (8-9).

To date, psychological and cognitive factors in studies of women with family histories of breast cancer has largely been based on samples of White women. Initial findings in samples of Black women with family histories of breast cancer suggest that, like White women, they perceive themselves to be at higher risk for developing the disease (11). In a study of 60 African-American, low-income women with family histories of breast cancer, the majority (55%) perceived themselves to be at risk for developing breast cancer and half reported being at least somewhat concerned about their chances of developing breast cancer (12). Bowen also found that Black women exhibited particularly high levels of perceived risk for breast cancer (13). When Black women with family histories of breast cancer were compared to their White counterparts, Hughes and colleagues (1996) found that Black women: 1) exhibited significantly

greater concerns about their personal risk of breast cancer and worries about their affected relative; and, 2) had higher cancer-specific distress (14).

Distress and breast self-examination

Psychological distress among women with family histories of breast cancer is not only clinically significant in its own right, it may also have an impact on breast cancer screening behaviors. Kash and colleagues (1992) found that higher levels of cancer-specific distress among women at familial risk to be related to poor compliance with clinical breast examinations, as well as poor compliance with recommended monthly breast self-examination (BSE) (6). Similarly, Benedict and colleagues (1997) found a significant inverse relationship between fear of breast cancer and frequency of breast self-examination among daughters of women diagnosed with breast cancer (15).

BSE over-performance has also been linked to higher psychological distress. Lerman and colleagues (1994) found that higher levels of psychological distress among women with family histories of breast cancer was associated with both insufficient and excessive breast self-examination behavior (> once a month) (7). A more recent investigation of predictors of BSE over-performance among women at familial risk (16) found that African-American women were over-represented in the group of women who over-performed BSE, and that over-performers were more likely to frequently think about breast cancer. Similarly, Royak-Schaler et al., (1995) found that perception of risk was related to breast cancer screening practices for African-American women under 50 years old; they were the most likely to have obtained a CBE and mammogram (12).

To our knowledge, the present study is the first to compare Black women with family histories of breast cancer to those without family histories of breast cancer on perceived risk, psychological distress and compliance with breast self-examination guidelines. The inclusion of a comparison group without breast cancer in first-degree relatives provides an important benchmark against which to assess both cancer-specific and general distress as well as BSE frequency. Most studies which have found that psychological distress and intrusive thoughts about breast cancer relate to inappropriate breast self-examination did not include a comparison group making it impossible to examine family history related differences in distress and BSE. Since the media has recently focused so much attention on breast cancer awareness it may be that women without a family histories of breast cancer also experience distress and intrusive thoughts about breast cancer which may be sufficient to impact on proper breast self-examination. Based on the literature reviewed above, we hypothesized that Black women with family histories of breast cancer would score higher on measures of distress than Black women without family histories of breast cancer and that psychological distress would predict poor compliance with recommended breast self-examination guidelines.

Method

Participants

Black women with (Risk Group, N=23) and without (Comparison Group, N=32) family histories of breast cancer were recruited for the present study. Women in the Risk Group had at least one first-degree relative with breast cancer. Women in the Comparison Group had no first-degree relatives with breast cancer. Women were excluded if they: 1) were unable to speak or

read English; 2) were less than 25 years old; 3) were unable to give meaningful informed consent; 4) had a history of neoplasm of an abnormal pathologic report; 5) were pregnant; 6) had evidence of abnormal results on their most recent mammogram.

Setting

All participants were recruited from an inner-city cancer screening center in New York City -- (The Breast Examination Center of Harlem; BECH, a community program of Memorial Sloan-Kettering Cancer Center). The BECH provides advanced, comprehensive diagnostic cervical and breast screening services to women of the Harlem community. All services (e.g., mammogram, pap smear, clinical breast exam) are provided at no out-of-pocket expense to the client. Women who attend the BECH are instructed in how to perform BSE and receive routine clinical breast exams at every screening visit.

Procedures

In person contact was made with the women at the breast clinic and the study was described. All data for this study were collected as part of a larger investigation of psychobiological factors associated with having a family history of breast cancer. Interested women were then scheduled to meet with study personnel at least one month after the initial contact, because we have previously documented high levels of acute distress on the day of mammography screening (8). At their scheduled appointment, participants were asked to read and sign the consent forms and were given standardized measures that included cognitive and psychological variables. Each woman took approximately 60-minutes to complete the questionnaires. As a consideration to participants, additional questionnaires that assessed breast

cancer screening behaviors and demographic data were given to participants to complete at home and return in a pre-paid mailer the next day (see Measures below). All participants were offered \$20 plus the cost of public transportation to and from the study site.

Measures

Demographic and medical questionnaire. A standard questionnaire was used to obtain information on age, race/ethnicity, education, marital status, employment, smoking, height, weight, and other health-related variables (9). Histories of cancer in the family were obtained using a self-report form (9,17).

General distress

Brief Symptom Inventory (BSI) (18). The BSI, a validated and highly reliable brief form of the classic SCL-90 (Symptom Checklist-90 revised), was used to provide an assessment of general distress over the past three weeks. The BSI has nine symptom dimensions and three global indices of stress symptomatology. To reduce the likelihood of type I error, only the General Severity Index (GSI) was analyzed for the current study. Because preliminary analyses indicated that scores on this index were not normally distributed, results were dichotomized (median split, .396) and subsequently analyzed with a non-parametric test (X^2).

Cancer-specific distress

Impact of Events Scale (IES) (19). The IES is a 15-item self-report inventory that assesses intrusive thoughts and avoidance. The scale items are anchored to a specific stressor (in this case, the threat of breast cancer) and yield subscores for intrusive and avoidance experience. This measure was chosen because it assesses symptoms reflective of current distress (19), and

because in studies of predominantly White samples it has revealed differences in cancer-specific distress between women with and without family histories of breast cancer (e.g., 8-9). The measure has also been used with Black women with family histories of breast cancer (14). Subjects were asked to rate how frequently each thought or behavior occurred during the past three weeks. Of particular interest in the present study was the intrusive thoughts subscale, as Lerman et al., (1993) have previously reported that women with family histories of breast cancer score especially high on this measure. Scores were not normally distributed and were dichotomized at the median (median split .396, T-score=54).

Perception of breast cancer risk

Perceived risk for cancer. Perceived risk for cancer was assessed by asking subjects to rate their perceived likelihood of developing breast cancer in their lifetime from 0% (not at all likely) to 100% (extremely likely) (8). Because preliminary analyses indicated that the data on this measure were not normally distributed, with approximately half the participants indicating that they were at 50% or greater risk, results were dichotomized (less than <50% lifetime risk and 50% or more lifetime risk).

Breast self-examination behavior

Assessment of breast self-examination. Participants were asked to respond to the following question: *How often do you perform breast self-examination?* on a seven-item measure ranging from 1- more than once a month to 7 - never. For statistical purposes, the scale was broken down into three sections 1) more than once a month (over-performers); 2) once a month (appropriate performers); and, 3) less than once a month - (under-performers). Accuracy of self-

reported breast screening has been validated among sociodemographically low-income, minority and diverse women (20-21).

Results

Demographic variables for the Risk and Comparison Groups are shown in Table 1. No significant differences between the groups were found. Consistent with their family histories of breast cancer, the Risk Group had a significantly ($t=3.14$, $p \leq .004$) higher objective risk of breast cancer than the Comparison Group, as determined by the Claus model (3) (see Table 2).

As shown in Table 2, women in the Risk Group were more likely to report high perceived risk than women in the Comparison Group (chi-square = 4.96, $p < .026$). The Risk Group was also significantly more likely to report intrusive thoughts about breast cancer than the Comparison Group ($p < .024$). These results support that, like predominantly White samples, Black women with family histories of breast cancer are more likely to have intrusive thoughts about breast cancer than Black women without family histories of breast cancer. General distress (GSI) did not differ between the groups.

The Risk and Comparison Groups did not significantly differ in frequency of breast self-examination. As shown in Table 2, only about 20% of the women adhered to recommended guidelines. Therefore, we examined if perceived risk and psychological distress predicted BSE frequency across both groups of women.

Although there was no significant main effect for perception of risk or intrusive thoughts on BSE frequency, there was a significant interaction between these two variables (see Table 3). In further analyses to explore the source of the interaction (see Table 4), we found that Black

women with high perception of risk and more intrusive thoughts were less likely to perform BSE according to American Cancer Society guidelines. Having a high perception of risk and high intrusive thoughts predicted both BSE under- and over-performance (chi-square 11.556 $p < .003$). Among women with low perception of risk and no intrusive thoughts, no significant differences were found (chi-square 3.31 $p < .191$).

Discussion

This study sought to contribute to the literature in several ways. First, we examined the psychological impact of having a family history of breast cancer in a sample of African-American women through the inclusion of a comparison group without family histories of breast cancer recruited from the community. To our knowledge, this study is the first to utilize a comparison group in a solely Black sample to examine perceived risk, psychological distress and their relationship to breast self-examination behavior.

Second, we conducted concurrent assessments using standardized measures of cancer-specific distress, (IES), and general distress (GSI). Third, we recruited women from a facility that offers free breast and cervical cancer screening and provides written, video-taped and hands-on instruction in appropriate breast-self examination. In so doing, we sampled from a population that presumably knows how and when to perform BSE.

We found that Black women with family histories of breast cancer (Risk Group) were significantly more likely to have high perceptions of their breast cancer risk and higher levels of intrusive thoughts about breast cancer than those without a FDR with breast cancer. Unlike some previous studies with predominantly White participants (6,8), we did not find that having a family

history of breast cancer by itself was associated with greater general psychological distress.

The finding that the Risk Group had a higher perception of personal risk is consistent with previous findings (22-24), but we did not find that having a family history was associated with adherence to BSE screening guidelines. Our findings would seem to be at odds with those of Nemcek (1989) who reported that the experience of having a close family member or friend battle breast cancer encouraged BSE frequency among Black women. In that study, Black women who were "directly-exposed" to someone with breast cancer were significantly more likely to perform BSE than Black women who were not exposed to the disease (25). One might imagine that having a first-degree relative with breast cancer (as our Risk Group) "directly-exposes" a woman to breast cancer, but we did not directly assess such interactions in this study. Our findings are consistent with those of Alagna et al. (1987) in a study which compared women at high familial risk of breast cancer (five or more relatives with breast cancer), to women at low risk for breast cancer (no breast cancer in immediate family members) and found that high risk women were more knowledgeable about BSE, but did not significantly differ from the low risk group on BSE frequency (26). In that study, participants' race were not reported.

Our results should also be compared to those in the literature regarding the importance of perception of risk and intrusive thoughts on BSE frequency. Interestingly, in the present study it was the interaction of intrusive thoughts and perception of risk that predicted BSE across the Risk and Comparison Groups. We found that women with high perceptions of risk and high intrusive thoughts were less likely to adhere to BSE guidelines. They either under- or over-performed BSE. This finding is consistent with a study by Lerman et al. (1994) which found that

a subset of younger women with family histories of breast cancer were practicing BSE excessively, and this was related to intrusive thoughts about developing breast cancer. Levels of generalized psychological distress were highest among women who never practiced BSE or practiced less than once per month (7)

In light of cultural, social and economic differences between Black and White women, it will be important in future studies to examine such factors as contributors to the relationship between family history, psychological distress, perceived risk and BSE frequency. For example, it may be that having a family history of breast cancer psychologically impacts Black women differently than White women. Hughes et al (1996), found that Black women with a family history of breast cancer were significantly less likely than White women to report heightened perception of personal risk after their relative was diagnosed with breast cancer (61% versus 82%; $p < .001$). The Black women in that study also differed significantly from the White women in BSE frequency; the Black women were more likely to perform BSE excessively. It may be that Black women in general over-perform BSE. In our study, with an entirely Black sample, we found a high incidence of excessive BSE (43% of the Risk Group and 38% of the Comparison Group).

The importance of appropriate, monthly BSE should not be minimized for several reasons. First, BSE is a no-cost health behavior that may empower and motivate women to perform other cancer screening behaviors. For example, a recent study found that Black women who were under-screened or unscreened for mammography were twice as likely to be those who performed BSE infrequently or not at all (27). In another study, performing regular BSE was associated

with higher rates of mammography screening (28). And still a third study (29) found an association between monthly BSE and recency of Pap test. Second, Black women present with later-stage breast disease than White women (30). This finding is likely to be related to a host of variables including cultural and social barriers (30), but the major factor is thought to be the lower socioeconomic status of Black women as a whole which makes access and quality care less available (31).

Third, there is evidence that performing certain components of BSE (visual examination of the breasts, palpation with finger pads, and examined breasts with three middle fingers) reduced the risk of dying from breast cancer (32). Although mammogram is the most frequent method of breast cancer discovery, BSE has been found to run a close second (33). Finally, according to Epstein, et al. (1997) over performance of BSE may increase the likelihood false-findings, with attendant high anxiety and reduced adherence to appropriate BSE.

Understanding BSE frequency among Black women may help explain why Blacks, who are less likely to develop breast cancer, have a lower five-year survival rate than Whites once diagnosed (34). Later stages at diagnosis and delay in seeking treatment once symptoms are present (35-36) appear to explain Black/White mortality differences. Low-income and minority women have been found to delay seeking treatment out of fear, marginal access to medical care, and procrastination (37). As it has been reported that women are more likely to seek help for potential breast cancer if they are BSE performers and users of mammograms (38) and because there is evidence which suggests that regular and proper BSE may reduce breast cancer mortality by 18% (39), it is important that Black women, particularly those with a family history of breast

cancer, utilize every defense available to them against breast cancer, including BSE. The present study is another step in understanding possible psychological barriers to compliance with BSE guidelines among Black women.

Abstract

Although breast self-examination (BSE) is a strongly recommended method of early breast cancer detection, a majority of women do not comply with the established performance guidelines of monthly BSE. Studies have identified a number of sociodemographic and health belief variables that relate to BSE frequency, but few have examined the impact of psychological distress. It may be particularly important to examine the role of distress in the recently identified phenomenon of BSE over-performance ($>1/\text{month}$). The present study aimed to assess the impact of psychological distress and health beliefs on BSE under-performance and over-performance. One hundred thirty-five healthy women with and without family histories of breast cancer completed sociodemographic, health belief, psychological distress, and BSE frequency questionnaires. Consistent with previous findings, over a third of the women under-performed BSE and over a quarter of the women over-performed BSE. The central finding of the study was that BSE under-performance and over-performance had two distinct sets of predictors: Health beliefs, specifically barriers against BSE and confidence in BSE performance, were related to BSE under-performance, while psychological distress, particularly cancer-specific intrusive thoughts, was related to BSE over-performance. These findings are important in that they underscore the importance of cancer-specific intrusive thoughts in women who over-perform BSE and poor health beliefs in women who under-perform BSE, factors that can be potentially critical in the successful development of specific interventions and educational programs aimed at increasing compliance with recommended BSE screening frequency.

Keywords: Psychological Distress, Health Beliefs, Breast Self-Examination, Detection

Psychological Distress, Health Beliefs, and Frequency of Breast Self-Examination

Breast cancer is currently one of the most frequent causes of mortality among women in the United States (1). The disease is chronic and often debilitating, taking its toll on both the patient and her family members. Although curative treatment for breast cancer is increasingly successful, early detection and subsequent early intervention are critical in reducing mortality rates among women (1,2). Of the three commonly employed methods of early breast cancer surveillance (clinical breast examination, mammography, and breast self-examination), only breast self-examination (BSE) entails that the individual independently perform a surveillance behavior on a monthly basis. The other forms of surveillance occur at most annually or biannually, and are performed by a health care professional. BSE is an inexpensive and convenient method of breast cancer surveillance, may often be the only screening method available for women without access to professional health care services, and may be more useful than mammography in detecting lumps in younger women with thicker breast tissue (1). Although its efficacy in reducing mortality has been challenged by some (3), BSE is reasonably successful in early detection of breast tumors according to a number of studies (4) and is strongly recommended by the American Cancer Society (1) for all women over age 20. Nevertheless, research continues to indicate that the majority of women in the U.S. do not perform BSE as often as the recommended monthly interval (5).

Of recent interest has been the identification of a substantial subset of individuals who actually over-perform BSE [i.e., >1/month] (6). Over-performance of BSE is not only time consuming, but may also limit its utility as a screening tool because of the possibility of decreased

sensitivity to gradual changes, in conjunction with the potential for a less thorough performance of each examination as the number of examinations increase (7). Indeed, in the seminal paper recommending regular BSE, Haagensen (8) suggested that BSE over-performance may be counterproductive, and that BSE performance at the same stage in the menstrual cycle each month is optimal in becoming accustomed to the feel of breast tissue.

A number of recent studies have aimed to identify sociodemographic factors that may predict frequency of women's BSE performance, in the hopes of providing means for better targeting individual and community-wide intervention and education efforts. For example, some studies have suggested that African American women are more likely to under-perform BSE than Caucasian women (9), while one recent large-scale study concluded that African American women were more likely to over-perform BSE (10). Similarly, there is mixed support for the impact of having a first degree relative with breast cancer on women's BSE frequency (10-12). Because African-American women and women at familial risk for breast cancer have higher mortality rates from breast cancer (1), identifying predictors of BSE frequency in these women is particularly important. Other variables reported to be associated with BSE under-performance include age, education and marital status (13,14). However, studies to date have largely examined sociodemographic correlates of BSE under-performance with little attention given to the correlates of BSE over-performance [see (10) and (15) as exceptions].

In addition to studying the impact of sociodemographic variables on BSE frequency, recent investigations have explored variables derived from Rosenstock's (16) Health Belief Model. The Health Belief Model and recent modifications (17-19) theorize that five factors relate to the

performance of a surveillance behavior: perceived seriousness of the disease, perceived susceptibility to the disease, perceived benefits of engaging in the surveillance behavior (early detection, decreased mortality, etc.), perceived barriers to engaging in the behavior (time consuming, embarrassing, etc.), and confidence in correctly performing the surveillance behavior to maximize its utility.

Numerous studies of Health Belief variables have found that greater perceived barriers to BSE predicted under-performance (5,18,20-22); fewer perceived benefits have been more equivocally related to BSE under-performance. Lower confidence in one's ability to perform BSE predicted under-performance in a number of studies (5,13,21,23-26). Lower perceived susceptibility also predicted BSE under-performance in several studies (5,11,18,21,22,27). Finally, lower perceived seriousness predicted BSE under-performance in two studies (18,21). To our knowledge, no previous studies have examined the possible roles of Health Belief variables in predicting BSE over-performance.

Although studies based on the Health Belief Model have sometimes assessed certain types of psychological distress related to screening behaviors (such as fear of finding a lump--an Health Belief Barrier), formal assessments of general and cancer-specific distress and their relationships to BSE frequency are rare in the literature. One study found that general psychological distress measured by the Brief Symptom Inventory [BSI] (28) correlated negatively with BSE frequency (15). Other studies have found that cancer-specific distress, such as intrusive thoughts about breast cancer, correlated positively with BSE frequency (27,29), but BSE over-performance was not examined. Epstein and colleagues (10) found that high levels of cancer-specific distress

correlated with BSE over-performance. Lerman and colleagues (15), the first to concurrently assess both BSE over-performance and under-performance, found that psychological distress measured by a global score on the BSI related to BSE under-performance, and that cancer-specific distress related to BSE over-performance in women with family histories of breast cancer. The literature thus remains equivocal in terms of the role of psychological distress in predicting BSE frequency, especially BSE over-performance, and replication remains scarce. Additionally, the predictive value of psychological distress beyond what can be attributed to classic Health Belief variables has yet to be examined.

To our knowledge, the study reported here is the first to examine psychological distress, as well as health beliefs, family history, and sociodemographic variables as possible predictors of BSE under-performance and over-performance. These factors were assessed contemporaneously to facilitate analysis of the unique contributions of psychological distress to the prediction of BSE frequency, allowing a more encompassing picture of the factors associated with women's compliance to the recommended guideline of monthly BSE. In light of recent findings that women with family histories of breast cancer and African American women may be less likely to comply with recommended guidelines for monthly BSE, we targeted recruitment to ensure representation of these groups in the study. We hypothesized that psychological distress, health beliefs, breast cancer risk factors, and sociodemographic variables would predict BSE frequency when considered separately. To provide a critical test of the impact of psychological distress above and beyond other predictors, we examined the possibility that psychological distress would predict BSE frequency even after accounting for factors in the Health Belief Model. Based on the

reports by Epstein et al. (10) and Lerman et al. (15), we hypothesized that high cancer-specific distress would predict BSE over-performance, and that African American women would be over-represented in the subset of women who over-performed BSE.

Method

Subjects

One hundred thirty-five women with (n=51) and without (n=84) first degree relatives with breast cancer participated in the study. Subjects were screening participants (n=80), staff members (n=8) and volunteers (n=47) from breast cancer screening clinics in the greater New York City area and were participating in this study as part of a larger project assessing the psychobiological effects of stress. Screening participants, staff members, and volunteers did not differ in demographics, health beliefs, distress, or BSE frequency ($p>.20$). Because we aimed to oversample African American women and women with family histories of breast cancer, recruitment advertisements encouraged these women to participate. All women were healthy by self-report and had shown no evidence of cancer at the time of the assessment. Women taking any medications or suffering from chronic illness were excluded from the study. Over a third of the sample had family histories of breast cancer; two thirds were minority participants; about half had completed college; a third were currently married (see Table 1).

Measures

Subjects completed questionnaires assessing demographics and family history of cancer. They also reported possible risk factors for breast cancer, including age at menarche, age at first live birth, and number of children (30). In addition, subjects completed health belief questionnaire

items adapted from Champion (18). Perceived seriousness was assessed by having subjects rate "how serious of a disease do you think breast cancer is" on a scale from 0 ("not serious at all") to 100 ("as serious as can be"). Perceived susceptibility was assessed by having subjects rate "how likely do you think you are to develop breast cancer in their lifetime" on a scale of 0 ("not at all likely") to 100 ("extremely likely"). They also rated the degree to which they agreed with the benefits of BSE performance ("helps detect breast cancer early," "may relieve anxiety," etc.) and the barriers to BSE performance ("embarrassing," "time consuming," etc.) on a Likert-type scale of 1 (strongly disagree) to 5 (strongly agree), based on benefits and barriers reported in a number of recent studies (31,32). Subjects also reported on a Likert-type scale of 1 to 5 how confident they were in their ability to adequately perform BSE.

General psychological distress over the past month was measured using the Brief Symptom Inventory [BSI] (28). As an additional measure of distress, mood disturbance on the day of assessment was measured using the short version of the Profile of Mood States [POMS-SV] (33). To simplify analyses, only total scores on the BSI and POMS-SV were used. Cancer-specific distress was measured using the Impact of Events Scale [IES] (34), which is comprised of two subscales: intrusive thoughts and avoidance. "Breast Cancer" served as the "event" on the IES. Finally, as additional measures of "cancer-screening-specific" distress, subjects rated the degree to which they experienced distress when thinking about BSE and when performing BSE. They were instructed to mark a 100 mm line anchored by "Not at All Upset" on the left to "As Upset as I Could Be" on the right. To minimize retrospective bias, these items were only

completed by subjects who performed ($n=92$) or thought about performing ($n=96$) BSE within the previous three weeks.

To assess compliance with the recommended guideline of monthly BSE (1), we asked subjects to indicate how frequently they performed BSE over the past 12 months, according to the following categories: never, once per year, once every six months, once every two months, once per month, or more often than once per month. Consistent with recent studies (29,35), we categorized appropriate performance as once per month or once per 2 months (to allow for regular BSE performers who may occasionally miss some performances), BSE under-performance as less often than every other month, and BSE over-performance as more often than monthly (15).

Procedures

Subjects provided informed consent prior to participation. Questionnaires were completed in the presence of an investigator who was available to clarify any items, though they were permitted to complete the demographic portion of the questionnaire at home and return it in a prepaid mailer. Subjects were offered \$20 plus the cost of public transportation to and from the study visit.

Data Analysis

Following the methodology of Lerman et al. (15), our primary approach was to compare subgroups of women who: a) under-performed b) over-performed or c) met performance guidelines for monthly BSE. Preliminary analyses evaluated each continuous predictor variable for normality, and variables which failed to meet criteria (seriousness, susceptibility, confidence,

and distress variables) were dichotomized. In line with methodology of previous studies (15), perceived seriousness (Med.=100; M=92.7, SD=15.2) and susceptibility (Med.=50; M=38.6, SD=30.0) were dichotomized at the median. As indicated, half of the women perceived breast cancer as “extremely serious,” and half of the women rated their susceptibility to developing breast cancer in their lifetimes as “50” or greater. To facilitate chi-square and polychotomous logistic regression analyses, we generated a dichotomous “confident/not confident” variable from the original BSE confidence item. BSI Global Severity Index (Med.=0.32; M=0.44, SD=0.43), POMS (Med.=24, M=30.8, SD=23.1), IES Intrusive thoughts (Med.=2; M=4.1, SD=6.5), IES Avoidance (Med.=2, M=5.7, SD=8.8), Distress Thinking of BSE (Med.=5, M=14.3, SD=23.0), and Distress Performing BSE scores (Med.=5, M=16.5, SD=23.6) were all dichotomized at the median, as well. The distress variables were all positively skewed, with many subjects reporting no distress. Univariate analyses on categorical and dichotomous variables were conducted using the chi-square statistic. Continuous variables (current age, age at menarche, age at first live birth, number of children, perceived benefits and perceived barriers) were analyzed using the one-way ANOVA technique with Duncan's (36) pairwise comparison test. Unique contributions of the psychological variables were assessed with a polychotomous hierarchical multiple logistic regression analysis [used when the dependent variable has more than two levels, as in the present study assessing under-, appropriate- and over-performance of BSE] (37). All statistical tests were two-tailed.

Results

Findings indicated that 36% (n=49) of the women met recommended guidelines for monthly BSE, while almost an equal number of women under-performed BSE (36%, n=48), and 28% (n=38) of the women over-performed BSE. Univariate analyses of the relationships between BSE frequency and demographics, health beliefs, and psychological distress are presented below.

Demographics

As indicated in Table 2, when considered individually, age, level of education, and ethnicity were related to BSE frequency. The mean age of Under-Performers (38.9, SD=9.3) did not differ from that of Appropriate-Performers (42.2 years, SD= 11.3), but did differ ($p<.05$) from that of Over-Performers (44.2 years, SD=8.9). Additionally, significantly more Under-Performers and Appropriate-Performers completed college than did Over-Performers ($p<.05$). Consistent with earlier research, significantly more Over-Performers were African American than Appropriate- Performers ($p<.10$) and Under-Performers ($p<.05$) . A trend suggested that Under-Performers were more likely to have incomes of above \$40,000 than Appropriate Performers ($p<.10$). Marital status was not related to BSE frequency in this sample. Having a family history of breast cancer in one or more first degree relatives, having an objective lifetime risk greater than the base rate [Claus model (38)], and having other objective risk factors for breast cancer were also not related to BSE frequency. These findings are consistent with a number of recent studies failing to support the hypothesis of risk-related differences in BSE behavior (12).

Health Beliefs

As indicated in Table 3, perceived seriousness, perceived barriers, and confidence in BSE performance were related to BSE frequency. Under-Performers were less likely to perceive breast cancer as being extremely serious than Appropriate-Performers ($p < .10$) and Over-Performers ($p < .05$). Under-Performers were also less likely to report being confident in BSE performance, and scored higher on the Perceived Barriers scale than Appropriate-Performers and Over-Performers ($p < .05$). Over-Performers did not differ from Appropriate-Performers on any of the health belief variables. Interestingly, perceived risk and perceived benefits were not related to BSE frequency.

Psychological variables

As indicated in Table 4, breast cancer-specific intrusive thoughts and avoidance were related to BSE over-performance. Seventy six percent of Over-Performers had high intrusive thoughts of breast cancer, significantly more than either Appropriate Performers or Under-Performers. Similarly, 76% of Over-Performers had high avoidance, significantly more than Appropriate-Performers or Under-Performers. Distress during BSE showed a trend toward relating to BSE over-performance: 53% of Over-Performers reported high levels of emotional upset during BSE compared to 34% of Appropriate-Performers and only 25% of Under-Performers. General distress (BSI Global Severity Index) and acute mood disturbance (POMS-SV) were not related to BSE frequency.

Hierarchical Model

To determine the unique contributions of the psychological variables to BSE frequency, a polychotomous hierarchical multiple logistic regression was performed, using BSE frequency as the outcome variable. Our strategy was to enter demographic variables first, then Health Belief variables to identify the contribution of Health Belief factors after accounting for demographics, and finally, to enter psychological variables, to identify their unique contribution to BSE behavior after accounting for both demographics and health beliefs (Table 5). Variables that reached a significance level ($p < .10$) in the univariate analysis were entered into the regression. When demographic variables (age, education, income, and ethnicity) were entered in the first block, education significantly predicted BSE; $\chi^2 = 8.0$, $p < .005$. Health belief variables that were significant in the univariate analyses (seriousness, barriers, confidence) were entered in the second block. Results indicated that barriers and confidence were significantly related to BSE even after accounting for education; χ^2 change = 17.2, $p < .005$. In the final block, the significant psychological variables (intrusive thoughts, avoidance, and emotional upset when performing BSE) were entered. Results indicated that the intrusive breast cancer thoughts and emotional upset during BSE continued to be significantly related to BSE frequency even after accounting for the demographic and health belief variables; χ^2 change = 13.9, $p < .005$.

Discussion

The present study examined the impact of sociodemographics, health beliefs, and psychological distress on adherence to BSE at the recommended monthly interval. To our knowledge, this is the first study to assess the unique contribution of psychological distress as a

predictor of BSE frequency over and above contributions from other variables. In addition, this is the first study to contemporaneously examine these variables' impact on both BSE under-performance and over-performance. Findings indicated that BSE under-performance was related to higher income, higher perceived barriers, lower confidence in performing BSE, and marginally related to lower perceived seriousness. On the other hand, BSE over-performance was related to not completing college, higher cancer-specific distress, higher distress during BSE, and marginally related to African American ethnicity. Hierarchical models suggested that education, barriers, confidence, and cancer-specific distress were the contributors to variance in BSE frequency, and that cancer-specific distress was related to BSE even after accounting for the contributions of the other variables. This is consistent with the finding that distress was related to over-performance, while the Health Belief variables were related to under-performance.

In agreement with previous research, the present set of findings suggests that the Health Belief Model is important in predicting BSE, but not all of its components have predictive power, and not all of the variance in BSE is accounted for by the model. Interestingly, the Health Belief variables only predicted BSE under-performance in this sample, suggesting that health beliefs do not account for the phenomenon of BSE over-performance. Cancer-specific psychological distress, on the other hand, did relate to BSE over-performance in our sample.

Our finding that twenty eight percent of women performed BSE more often than monthly is consistent with Lerman et al. (15) who found that 15-36% of their samples of women with family histories of breast cancer were Over-Performers. Indeed, Epstein et al. (10) reported that 8% of women performed BSE daily. Future studies investigating BSE frequency within the

subset of over-performing women may be useful in determining whether or not women who perform BSE daily differ from those who over-perform less markedly.

The present finding that women who over-perform BSE differ from women who appropriately-perform BSE also suggests that future studies should not combine these two groups and simply compare them to women who under-perform BSE. For example, in the present study, if we were to have compared the Under-Performers to the combined group of Appropriate-Performers and Over-Performers, we might have erroneously concluded that women who under-performed BSE were characterized by lower levels of cancer-specific intrusive thoughts, when in reality, the percentage of Under-Performers and Appropriate-Performers who exhibited intrusive thoughts were almost identical (Table 4). Hence, examining Over-Performers separately from Appropriate-Performers not only yields valuable information about BSE over-performance, but also allows for more accurate conclusions about characteristics of women who under-perform BSE.

Although studies have not yet been conducted to formally establish negative consequences of BSE over-performance, a number of such consequences are potentially important (10). First, it is not unreasonable that performing BSE too often may render a woman less sensitive to the gradual changes characteristic of tumor development, thus decreasing the likelihood of detection. Additionally, women who over-perform BSE may perform each exam in a more cursory fashion, decreasing the likelihood of detection (7). Alternatively, as suggested by Epstein et al. (10), BSE over-performance may lead to an increased number of "false-alarm" detections, which may ultimately result in a lack of confidence in detecting or reporting lumps in the future. Finally, pre-

menopausal women who perform BSE several times a month during which breast tissue can undergo palpable, menses-related changes may experience difficulty differentiating between so-called "normal" changes and abnormal changes in breast tissue (8). Thus, it is possible that BSE over-performance may lead to an increase in "false-negative" detections or an increase in "false-alarm" detections. Both false-alarm and false-negative detections can be potentially dangerous errors in the early detection of breast cancer (1). Future research should examine these possible negative implications of BSE over-performance.

In this sample, women with family histories of breast cancer were no more likely to perform BSE at the recommended monthly interval. It should be noted that in the present study, women were recruited from breast cancer screening clinics and medical center staff. Such women are likely to be aware of the need for breast cancer screening, yet, surprisingly, many of them were noncompliant to BSE at the recommended monthly interval. The possibility, thus, exists that noncompliance may be even greater in the general population. Because women with family histories are at greater risk to develop breast cancer, research and intervention efforts should focus on increasing compliance to screening guidelines in this population. The present findings suggest that such efforts might most profitably be focused on removing perceived barriers, increasing BSE confidence, and alleviating cancer-specific distress.

It must be emphasized that the present findings are correlational, and, thus, cannot formally demonstrate that the relationship between cancer-specific distress and BSE over-performance is causal in nature. It is also possible that BSE over-performance generates the cancer-specific distress observed in this sample. A third possibility is that BSE is both distressing

in itself and maintained by women's distress about their risk. A vicious cycle may develop in which BSE performance causes cancer-specific distress, which in turn stimulates additional examinations, and so forth. Indeed, since the inception of BSE as a screening method, clinicians have been wary of the "cancerphobia" that may be related to over-performance (8).

In sum, the present study is consistent with an emerging body of evidence suggesting that BSE over-performance may be a prevalent problem. Our study indicated that BSE over-performance has fundamentally different predictors than BSE under-performance. These findings suggest that Over-Performers comprise a distinct group of women and should not be simply combined with Appropriate-Performers in comparison to Under-Performers, as has been done in previous studies. Such oversimplification may lead to misleading and erroneous conclusions about predictors of under-performance as well as failure to characterize the potentially unique profile of women who over-perform BSE.

Table 1.
Subject Characteristics: Demographics and Risk Factors

Mean Age in Years	41.6 (SD=10.1)
Education (%completed college)	53%
Income (% earning above \$40,000.00)	39%
Marital Status (% married)	33%
Ethnicity (% Caucasian)	30%
Familial Risk (% with a FH of breast cancer)	38%
Objective Risk (% with Claus Score >11)	30%
Mean Age at Menarche	12.4 (SD=1.9)
Mean Age at First Live Birth	23.4 (SD=5.6)
Mean Number of Children	2.7 (SD=1.7)

Table 2.
Bivariate Associations Between Subject Characteristics and BSE Frequency

Variable	Under- Performance (n=48)	Appropriate Performance (n=49)	Over- Performance (n=38)
Mean Age in Years	38.9 ^a (SD=9.3)	42.2 (SD=11.3)	44.2 ^a (SD=8.9)
Education (% completed College)	65% ^a	57% ^b	32% ^{a,b}
Income (% above \$40,000.00)	50% ^c	30% ^c	35%
Ethnicity (% African American)	44% ^a	55% ^c	74% ^{a,c}
Family History (% with a FH of breast cancer)	38%	31%	47%
Objective Risk (% with Claus score >11)	31%	26%	32%
Mean Age at Menarche	12.2 (SD=1.9)	12.5 (SD=1.9)	12.6 (SD=1.8)
Mean Age at First Live Birth	24.4 (SD=5.1)	23.0 (SD=5.8)	22.7 (SD=5.9)
Mean Number of Children	3.0 (SD=2.0)	2.2 (SD=1.6)	2.8 (SD=1.2)

^{a,b}Values in each row with matching superscripts differ significantly at $p < .05$

^cValues in each row with matching superscripts differ significantly at $p < .10$

Table 3.
Bivariate Associations Between Health Belief Variables and BSE Frequency

Variable	Under- Performance (n=48)	Appropriate Performance (n=49)	Over- Performance (n=38)
Perceived Seriousness (% above median)	56% ^{a,c}	73% ^c	79% ^a
Perceived Risk (% above median)	44%	57%	57%
Mean Perceived Benefits	3.9 (SD=0.6)	4.1 (SD=0.8)	4.0 (SD=0.8)
Mean Perceived Barriers	1.9 ^{a,b} (SD=0.7)	1.4 ^a (SD=0.6)	1.4 ^b (SD=0.5)
BSE Confidence (% reporting confidence)	33% ^{a,b}	59% ^a	57% ^b

^{a,b}Values in each row with matching superscripts differ significantly at $p < .05$

^cValues in each row with matching superscripts differ significantly at $p < .10$

Table 4.
Bivariate Associations Between Psychologic Distress and BSE Frequency

Variable	Under- Performance (n=48)	Appropriate Performance (n=49)	Over- Performance (n=38)
BSI Global Severity Index (GSI) (% scoring above median)	50%	52%	60%
POMS Acute Mood Disturbance (% above median)	37%	49%	50%
Intrusive Breast Cancer Thoughts (% above median)	42% ^a	46% ^b	76% ^{a,b}
Avoidance (% above median)	44% ^a	44% ^b	76% ^{a,b}
Emotional Upset During BSE** (% above median)	25% ^c	34% ^d	53% ^{c,d}
Emotional Upset Thinking of BSE (% above median)	52%	39%	51%

^{a,b}Values in each row with matching superscripts differ significantly at $p < .05$

^{c,d}Values in each row with matching superscripts differ significantly at $p < .10$

**only includes subjects who performed BSE in the past three weeks

Table 5.
Hierarchical Logistic Regression Predicting Breast-Self Examination Frequency

Significant Variables	Chi-Square	Univariate Odds Ratio (95% C.I.)
Step 1--Demographics	7.7	Over vs. Appropriate
Education		0.36** (0.15, 0.89)
Step 2--Health Belief Model	17.2	Under vs. Appropriate
Perceived Barriers		3.57** (1.61, 7.70)
BSE Confidence		0.34** (0.15, 0.79)
Step 3a--Psychologic Distress (All Subjects)	7.2	Over vs. Appropriate
Intrusive Breast Cancer Thoughts		3.81** (1.49, 9.74)
Step 3b--Psychologic Distress (Subjects who performed BSE in the past three weeks)	13.9	Over vs. Appropriate
Emotional Upset During BSE		2.16* (0.86, 5.40)
Intrusive Breast Cancer Thoughts		4.35** (1.55, 12.16)

**p<.005

*p<.10
